Abstract—This paper is on opportunistic relaying for networks with two-way communications. For a network with two users that exchange information with each other through multiple amplify-and-forward relays, we propose a single-relay selection scheme. Since the communication is two-way, the proposed scheme aims at optimizing the worse performance of the two communication tasks between the pair of users. An approximation on the cumulative distribution function (CDF) of the effective worse signal-to-noise ratio (SNR) of the two users using the proposed scheme is obtained, based on which the block error rate (BLER) and the diversity order of the two-way network are derived. Then, the single-relay selection scheme is generalized to a multiple-relay selection scheme with the help of the relay ordering idea. Numerical and simulation results are provided to verify the analysis.

Index Terms—Diversity, error rate, relay selection, two-way relay networks.

I. INTRODUCTION

Node cooperation has shown to be one of the most effective ways to mitigate the fading effect of wireless channels and achieve spatial diversity in a network. A lot of cooperative strategies have been proposed and their performances have been analyzed (e.g., [1]–[5]). Opportunistic relaying, or relay selection, is one type of cooperation schemes that attracts many interests. In comparison with other schemes, it usually achieves full diversity with less synchronization requirement and overhead. Based on the nature of the relay processing, two popular relaying strategies are decode-and-forward (DF), in which the relays decode the received signals and then forward the decoded information to the destination, and amplify-and-forward (AF), in which the relays amplify the received signals and forward them to the destination without a hard decoding [1]–[3]. For AF relaying, a coefficient is used at each relay to constrain its transmit power. Two types of power coefficients are proposed in the literature: the coherent power coefficient and the non-coherent power coefficient, depending on the available channel state information (CSI) at the relay [4], [5]. For one-way relay networks, in which transmission is from one end to the other through relays, relay selection schemes, or opportunistic relaying, such as the best relay selection, the nearest neighbor selection, the best worse channel selection, the maximum harmonic mean selection, etc., are proposed for both DF and AF relaying [6], [7].

Recently, two-way relay networks, or bi-directional relay networks, in which two end users exchange information with each other through a single or multiple common relays, have gained lots of attention. To accomplish the information ex-

change between the two end users in a network, the traditional one-way half-duplex scheme requires four channel uses, which is bandwidth inefficient. To improve bandwidth efficiency, a two-way relaying scheme that takes two channel uses only is proposed [8]–[10]. In this scheme, the channels between the source and the relays and between the relays and the destination are active at the same time. Research on relay selection in two-way relay networks, however, is still limited. Some preliminary research work can be found in [11]–[16]. In [11], a relay selection scheme which maximizes the weighted sum-rate capacity in a network with DF relaying is proposed. Based on both instantaneous channel conditions and the queuing status, a cross-layer relay selection metric is investigated in [12]. In [13], the best relay is defined as the relay that maximizes the instantaneous sum-rate function. In [14], a single-relay selection scheme is studied, which minimizes the sum symbol error rate (SER) of both end users. In [15], the relay selection and opportunistic source selection are optimally combined to maximize the mutual information for an AF-based bi-directional relay network. Recently, a single-relay selection scheme that maximizes the worse receive signal-to-noise ratio (SNR) of the two end users is proposed for networks with multiple AF relays in [16]. The error rate and diversity order of the network are rigorously analyzed for the high SNR regime.

This paper is on relay selection in two-way networks with multiple AF relays. It is a broader and deeper extension of the work in [16]. We first consider the scenario when only one relay is selected among all available relays, referred to as *single-relay selection*. For a two-way network with two relays under both the coherent and non-coherent power coefficients, a close approximation on the block error rate (BLER) of the overall network is provided based on an approximation on the cumulative distribution function (CDF) of the worse end-to-end SNR. Simulation and analysis show that the coherent power coefficient case always outperforms the non-coherent case. Then, we extend the single-relay selection scheme and analysis to a two-way network with an arbitrary number of relays. From the approximate BLER formula, diversity of the network is derived. After that, we propose a relay ordering function and consider the scenario where multiple relays can be selected, referred to as *multiple-relay selection*.

The remaining of the paper is organized as follows. The system model, relay selection criterion, and performance metrics are presented in Section II. The single-relay selection is studied in Section III and Section IV for networks with two

and an arbitrary number of relays, respectively. The multiple-relay selection is considered in Section V. Numerical and simulation results are presented in Section VI, followed by the concluding remarks in Section VII. An involved proof is provided in the appendix.

II. SYSTEM MODEL

Fig. 1. A two-way multiple-relay network.

A. Network Model and Formulation

Consider a two-way relay network with two end users (namely, U_1 and U_2) exchanging information through R relays (namely, r_1, \dots, r_R), as shown in Fig. 1. Each node has a single antenna for both transmission and reception. The fading coefficients between U_1 and r_i and between U_2 and r_i are denoted as f_i and g_i , respectively. All channels are assumed to be independent and identically distributed (i.i.d.) complex Gaussian fading with zero mean and unit variance, i.e., $f_i, g_i \sim \mathcal{CN}(0, 1)$. Therefore, magnitudes of f_i and g_i follow the Rayleigh distribution.¹ It is assumed that the two end users know all channel coefficients for decoding. This channel information requirement can be satisfied through training. The CSI requirement at each relay depends on the power coefficient design and will be clarified in Section II-B. The power budget is P for each end user, and Q_i for the i th relay.

For simplicity, we assume that both users use the same codebook denoted by \mathcal{S} . The information symbols of U_1 and U_2 are denoted by s_1 and s_2 , respectively. They are randomly selected from the codebook. To send s_1 from U_1 to U_2 and also send s_2 from U_2 to U_1 , we can use the following two-phase protocol. In the first phase, U_1 and U_2 transmit s_1 and s_2 , respectively, at the same time to all relays. Therefore, r_i receives the superposition of the two signals, given as

$$y_i = \sqrt{P}f_i s_1 + \sqrt{P}g_i s_2 + v_i. \quad (1)$$

¹Although the diversity and error rate analysis in this paper are for i.i.d. Rayleigh flat-fading channels only, the proposed relay selection schemes work for networks with any channel statistics, because the instantaneous CSI is assumed to be available at corresponding nodes.

The additive noise at the relays, v_i 's, are assumed to be i.i.d. circularly symmetric complex Gaussian random variables with zero mean and unit variance. In the second phase, one of the relays, say the j th relay r_j , is chosen, based on some relay selection strategy, to transmit (multiple-relay selection is to be discussed in Section V). With AF relaying, r_j simply amplifies y_j , and then forwards the signal to both users. If power coefficient α_j is used, the received signals at U_1 and U_2 are

$$\begin{aligned} y_{u_1,j} &= \alpha_j f_j (\sqrt{P}f_j s_1 + \sqrt{P}g_j s_2 + v_j) + w_1 \\ y_{u_2,j} &= \alpha_j g_j (\sqrt{P}f_j s_1 + \sqrt{P}g_j s_2 + v_j) + w_2, \end{aligned} \quad (2)$$

respectively. w_1 and w_2 denote the noises at the two users, and are assumed to be i.i.d. Gaussian with the distribution $\mathcal{CN}(0, 1)$. The equations show that each end user receives an observation that is a combination of the other user's symbol and its own symbol. After canceling the self-interference, U_1 and U_2 get

$$\begin{aligned} \tilde{y}_{u_1,j} &= \alpha_j \sqrt{P}f_j g_j s_2 + \alpha_j f_j v_j + w_1 \\ \tilde{y}_{u_2,j} &= \alpha_j \sqrt{P}f_j g_j s_1 + \alpha_j g_j v_j + w_2, \end{aligned} \quad (3)$$

respectively. The users use the following maximum-likelihood (ML) decoding rules to obtain estimations of the other user's symbol:

$$\begin{aligned} \hat{s}_2 &= \arg \min_{s \in \mathcal{S}} \left| \tilde{y}_{u_1,j} - \alpha_j \sqrt{P}f_j g_j s \right| \\ \hat{s}_1 &= \arg \min_{s \in \mathcal{S}} \left| \tilde{y}_{u_2,j} - \alpha_j \sqrt{P}f_j g_j s \right|. \end{aligned}$$

B. Relay Power Coefficient

In AF relaying, two types of relay power coefficients have been introduced for one-way relay networks: non-coherent power coefficient, and coherent power coefficient [17], [18]. Similarly, we can use the following two power coefficients at the j th relay in a two-way relay network.

- Non-coherent power coefficient: Relay j has knowledge of the average fading powers of its channels with each user, i.e., $\mathbb{E}[|f_j|^2]$ and $\mathbb{E}[|g_j|^2]$, and uses it to constrain its average transmit power. Therefore, α_j is given as

$$\alpha_j^2 = \frac{Q_j}{1 + P\mathbb{E}[|g_j|^2] + P\mathbb{E}[|f_j|^2]} = \frac{Q_j}{1 + 2P}. \quad (4)$$

Note that $\mathbb{E}[\cdot]$ denotes the expectation, and $|\vartheta|$ denotes the magnitude of a complex value ϑ .

- Coherent power coefficient: Relay j has knowledge of its instantaneous CSI with each user, i.e., f_j and g_j , and uses it to constrain its average transmit power. Therefore, α_j is given as

$$\alpha_j^2 = \frac{Q_j}{1 + P|f_j|^2 + P|g_j|^2}. \quad (5)$$

Note that to apply the coherent power coefficient, r_j only needs to know the magnitude of f_j and g_j . This is the CSI requirement at r_j for single-relay selection. For multiple-relay

selection, however, the channel phases are also required at the relay for the phase adjustment. The details are given in Section V.

An advantage of the non-coherent power coefficient over the coherent one is in its less overhead. It needs only the knowledge of the average fading powers, while the later needs the instantaneous CSI, which requires training and channel estimation at the relay. But for one-way relay networks, it has been shown that the coherent power coefficient has a better performance. Both power coefficients are considered in our research.

C. Relay Selection Criterion and Performance Measure

For one-way networks, the choice of the design criterion is straightforward. If reliability is of interest, usually, the goal is to minimize the error rate; or maximize the end-to-end SNR. For two-way communications, however, there are two communication tasks each with its own bit/symbol error rate and end-to-end SNR. The criterion is less straightforward. The choice depends on the overall network quality-of-service requirement and the fairness consideration. Maximizations of the sum and average error rates of two communication tasks are considered in [14]. In this paper, we care about the reliability of both users and propose to maximize the worse of the end-to-end SNRs of the two users, or equivalent, the larger of the error rates of the two communication tasks.

With single-relay selection, if r_j is chosen, the end-to-end SNRs of the two users are given as

$$\begin{aligned} U_1 : \quad \gamma_{u_1,j} &= \frac{PQ_j|f_jg_j|^2}{1 + 2P + Q_j|f_j|^2} \\ U_2 : \quad \gamma_{u_2,j} &= \frac{PQ_j|f_jg_j|^2}{1 + 2P + Q_j|g_j|^2}, \end{aligned} \quad (6)$$

for the non-coherent power coefficient case, and

$$\begin{aligned} U_1 : \quad \gamma_{u_1,j} &= \frac{PQ_j|f_jg_j|^2}{1 + (P + Q_j)|f_j|^2 + P|g_j|^2} \\ U_2 : \quad \gamma_{u_2,j} &= \frac{PQ_j|f_jg_j|^2}{1 + P|f_j|^2 + (P + Q_j)|g_j|^2}, \end{aligned} \quad (7)$$

for the coherent power coefficient case. In the second-phase of the network communication, we choose Relay \hat{i} , i.e., $r_{\hat{i}}$, if it results in the maximum worse end-to-end SNR, i.e.,

$$\hat{i} = \arg \max_j \min \{ \gamma_{u_1,j}, \gamma_{u_2,j} \}. \quad (8)$$

As to the performance measure, we consider the block error rate (BLER) and diversity order of the whole network. In a two-way relay network, the two users exchange their symbols, s_1 and s_2 , with each other. We can take s_1 and s_2 as a block (s_1, s_2) , and say that a block error occurs when either of the two users makes an error, i.e., $(\hat{s}_1, \hat{s}_2) \neq (s_1, s_2)$. Thus, the BLER metric is an upper bound on the SER of either user, and also a lower bound on the sum of the SERs of the two users. In addition, in the high SNR regime, the user with the worse SNR has a higher probability of making an error, and is the dominant reason of the block error. Thus, the metric

is consistent with the relay selection idea and criterion in (8). Later we will show that we can use the worse SNR analysis to approximate the BLER of the two-way network. The details are given in Section III.

Diversity order shows how fast the error rate decreases with the increase in the transmit power. It is conventionally defined as

$$d = - \lim_{P \rightarrow \infty} \frac{\log \text{Error rate}}{\log \text{Power}}.$$

Usually, the average error rate of a system can be approximated as

$$\text{Error rate} \approx cP^{-d} \quad (9)$$

where c relates to the array or coding gain, P is the transmit power, and d is the diversity order [19].

III. SINGLE-RELAY SELECTION IN A TWO-RELAY NETWORK

In this section, we consider a two-way network with two relays and analyze the performance of the proposed single-relay selection scheme for the two-way communication. Define $\gamma_j \triangleq \min \{ \gamma_{u_1,j}, \gamma_{u_2,j} \}$. Under the relay selection scheme given in (8), the worse end-to-end SNR can be written as $\gamma_{\hat{i}} = \max_j \gamma_j$, and $r_{\hat{i}}$ is chosen to cooperate. Since all channels are independent, if the CDF of γ_j is $F_{\gamma_j}(x)$, the CDF of $\gamma_{\hat{i}}$, denoted as $F_{\gamma_{\hat{i}}}(x)$, is $F_{\gamma_{\hat{i}}}(x) = F_{\gamma_1}(x)F_{\gamma_2}(x)$.

We will derive an average BLER approximation for the two-way network through the analysis on the CDF of the worse end-to-end SNR. For a given channel realization, let \hat{u} be the index of user with the worse receive SNR given that $r_{\hat{i}}$ is selected, i.e., $\hat{u} = 1$ if $\gamma_{u_1,\hat{i}} < \gamma_{u_2,\hat{i}}$ and $\hat{u} = 2$ otherwise. Let \tilde{u} be the index of the other user. The BLER can be calculated as follows.

$$P_{block} = \mathbb{E}[\mathbb{P}(\hat{s}_{\tilde{u}} \neq s_{\tilde{u}})] + \mathbb{E}[\mathbb{P}(\hat{s}_{\tilde{u}} \neq s_{\tilde{u}} | \hat{s}_{\hat{u}} = s_{\hat{u}})]. \quad (10)$$

\mathbb{P} indicates the probability. The first term is the average probability that the user with the lower SNR makes an error. The second term is the average probability that the user with the higher SNR makes an error given that the other user decodes correctly. When the transmit power is high, the second term is expected to be much smaller. Thus, we approximate the BLER as

$$P_{block} \approx P_{appro} = \mathbb{E}[\mathbb{P}(\hat{s}_{\tilde{u}} \neq s_{\tilde{u}})].$$

Since the second term in (10) is non-negative, P_{appro} actually provides a lower bound on the BLER of the network. From the definition, P_{appro} is exactly the average SER of a single-source communication system with receive SNR $\gamma_{\hat{i}}$. With digital modulations, the SER can be approximated as (the nearest neighbor approximation)

$$P_{appro} \approx M_{d_{\min}} \mathbb{E} \left[\mathbb{Q} \left(\frac{\beta}{\sqrt{2}} \sqrt{\gamma_{\hat{i}}} \right) \right],$$

where $M_{d_{\min}}$ is the number of neighbors a constellation point has at the minimum distance d_{\min} , β is a constant depending on the modulation, and $\mathbb{Q}(x)$ is the probability that a standard

$$I_1 = \frac{\sqrt{\pi}(3\rho^2+12\rho\eta^2+4\eta^4)e^{\frac{\eta^2}{\rho}} \operatorname{Erfc}\left(\frac{\eta}{\sqrt{\rho}}\right) - 2\sqrt{\rho}\eta(5\rho+2\eta^2)}{4P^2\rho^{\frac{9}{2}}}, \quad I_2 = \frac{\sqrt{\pi}(2(\rho-\frac{1}{P})+\eta^2)e^{\frac{\eta^2}{4(\rho-\frac{1}{P})}} \operatorname{Erfc}\left(\frac{\eta}{2\sqrt{(\rho-\frac{1}{P})}}\right) - 2\eta\sqrt{\rho-\frac{1}{P}}}{2P(\rho-\frac{1}{P})^{\frac{5}{2}}},$$

$$I_3 = -\frac{\pi U\left(\frac{1}{2}; 0; \frac{\eta^2}{4(\rho-\frac{1}{P})}\right)}{\sqrt{\rho-\frac{1}{P}}}, \quad I_4 = -\frac{\sqrt{2}\eta}{P\rho^2} G_{3,4}^{4,1}\left[\frac{\eta^2}{\rho} \left| \begin{matrix} -1, \frac{1}{4}, \frac{3}{4} \\ -\frac{1}{2}, 0, \frac{1}{2}, 1 \end{matrix} \right. \right], \quad I_5 = \frac{\sqrt{\pi}}{2\eta} G_{2,3}^{3,1}\left[\frac{\eta^2}{\rho} \left| \begin{matrix} 1, 2 \\ \frac{1}{2}, \frac{3}{2}, \frac{5}{2} \end{matrix} \right. \right].$$

normal random variable will obtain a value larger than x . Using integration by parts, we can show that

$$P_{\text{appro}} \approx \frac{\beta M_{d_{\min}}}{4\sqrt{\pi}} \int_0^\infty x^{-\frac{1}{2}} e^{-\frac{\beta^2}{4}x} F_{\gamma_1}(x) F_{\gamma_2}(x) dx. \quad (11)$$

Thus, given the CDFs $F_{\gamma_j}(x)$, one can calculate the approximate BLER using (11). In the following two sub-sections, we consider the non-coherent and the coherent power coefficients, respectively.

A. Non-Coherent Power Coefficient at Relays

Assume that each relay node uses a non-coherent power coefficient given in (4). The CDF of γ_j , $F_{\gamma_j}(x)$, is rigorously derived in the following theorem.

Theorem 1: With non-coherent power coefficient, the CDF of γ_j is

$$F_{\gamma_j}(x) = 1 - \eta_j \sqrt{x} e^{-\frac{x}{P}} K_1(\eta_j \sqrt{x}) + e^{-\frac{x}{P}} \int_{a_j - \frac{x}{P}}^{a_j} e^{-\left(y + \frac{\eta_j^2 x}{4y}\right)} dy \quad (12)$$

where $a_j = \frac{Q_j x + \sqrt{Q_j^2 x^2 + 4PQ_j(1+2P)x}}{2PQ_j}$, $\eta_j = 2\sqrt{\frac{1+2P}{PQ_j}}$, and $K_1(\cdot)$ is the modified first-order Bessel function of the second kind.

Proof: See the appendix. ■

We can further approximate the CDF in (12) for tractable BLER analysis using the mean value theorem. Let $\Lambda = [a_j - \frac{x}{P}, a_j]$. With the mean value theorem, there exists a $\mu \in \Lambda$ such that

$$\int_{a_j - \frac{x}{P}}^{a_j} e^{-\left(y + \frac{\eta_j^2 x}{4y}\right)} dy = \frac{x}{P} e^{-\left(\mu + \frac{\eta_j^2 x}{4\mu}\right)}.$$

Let $z = \frac{(1+2P)x}{PQ_j} \in \Lambda$. We have $|z - \mu| \leq x/P$. Since x/P is small for large P , $F_{\gamma_j}(x)$ in (12) can be approximated, by replacing μ with z , as

$$F_{\gamma_j}(x) \approx 1 - \eta_j \sqrt{x} e^{-\frac{x}{P}} K_1(\eta_j \sqrt{x}) + \frac{x}{P} e^{-\left(\frac{x}{P} + \eta_j \sqrt{x}\right)}. \quad (13)$$

For brevity, we assume that each relay node utilizes the same power, i.e., $Q_1 = Q_2 = Q$.² Thus, $\eta_1 = \eta_2 = 2\sqrt{\frac{1+2P}{PQ}} \triangleq \eta$.

An approximate closed-form average BLER can be calculated using (11) and (13) to yield

$$P_{\text{appro}} \approx \frac{M_{d_{\min}}}{2} + \frac{\beta M_{d_{\min}}}{4\sqrt{\pi}} \sum_{t=1}^5 I_t \quad (14)$$

²The case of unequal relay power can be analyzed similarly.

where I_t 's are given at the top of this page and $\rho = \left(\frac{2}{P} + \frac{\beta^2}{4}\right)$.

Note that the first term, $\frac{M_{d_{\min}}}{2}$, in (14) is a constant. But it will not result in an error floor because its value will be canceled out by other terms. The closed-form expression includes $U(\cdot; \cdot; \cdot)$, the confluent hypergeometric function of the second kind, $\operatorname{Erfc}(\cdot)$, the complementary error function, and $G[\cdot]$, the Meijer's G-function [20], which are available in computer software packages such as MATLAB and MATHEMATICA. We omit the detailed derivations due to the space limit.

B. Coherent Power Coefficient at Relays

Assume that each relay has a coherent power coefficient given in (5). The single-relay selection in a two-relay two-way network with the coherent power coefficient has been extensively studied in [16].

With a rigorous analysis, the CDF for $F_{\gamma_i}(x)$ is shown to be [16]

$$F_{\gamma_j}(x) = 1 - \frac{\kappa_j}{P} e^{-(1+2\xi_j)\frac{x}{P}} K_1\left(\frac{\kappa_j}{P}\right) + e^{-(1+2\xi_j)\frac{x}{P}} \int_{a_j - (1+\xi_j)\frac{x}{P}}^{a_j - \xi_j\frac{x}{P}} e^{-\left(y + \frac{\kappa_j^2}{4P^2y}\right)} dy \quad (15)$$

where $\xi_j = P/Q_j$, $\kappa_j = 2\sqrt{\xi_j x [1 + (1 + \xi_j)x]}$ and $a_j = \frac{(\xi_j + \frac{1}{2})x + \sqrt{(\xi_j + \frac{1}{2})^2 x^2 + \xi_j x}}{P}$. Using the mean value theorem for large P , we have

$$F_{\gamma_j}(x) \approx 1 - \frac{\tilde{\kappa}_j}{P} x e^{-\frac{\theta_j}{P}x} K_1\left(\frac{\tilde{\kappa}_j}{P}x\right) + \frac{x}{P} e^{-\frac{(\theta_j + \tilde{\kappa}_j)}{P}x} \quad (16)$$

where $\tilde{\kappa}_j = 2\sqrt{\xi_j(1 + \xi_j)}$, and $\theta_j = 1 + 2\xi_j$. In [16], the CDF is further approximated using $K_1(x) \approx 1/x$ by assuming that the transmit power of each node is high, i.e., $P, Q_j \gg 1$, to obtain

$$F_{\gamma_j}(x) \approx 1 - e^{-\frac{\theta_j}{P}x} + \frac{x}{P} e^{-\frac{(\theta_j + \tilde{\kappa}_j)}{P}x}. \quad (17)$$

The approximate BLER is then derived using (11).

Since the approximation $K_1(x) \approx 1/x$ is valid for large x only, results in [16] are limited to high power constraint at each node. In this work, we revisit the same problem, and derive an approximate BLER using (16), which is valid for any power constraint. Again, assume that each relay has the same power, i.e., $Q_1 = Q_2 = Q$. Thus, $\xi_1 = \xi_2 = P/Q \triangleq \xi$, $\kappa_1 = \kappa_2 = 2\sqrt{\xi(1 + \xi)} \triangleq \kappa$, and $\theta_1 = \theta_2 = 1 + 2\xi \triangleq \theta$. Using (11) and (16), an approximate average BLER expression

$$\begin{aligned}
J_1 &= \frac{\sqrt{\pi}}{P\left(\frac{\kappa}{P} + \frac{\theta}{P} + \frac{\beta^2}{4}\right)^{\frac{3}{2}}}, & J_2 &= \frac{3\sqrt{\pi}}{4P^2\left(\frac{2\kappa}{P} + \frac{2\theta}{P} + \frac{\beta^2}{4}\right)^{\frac{5}{2}}}, \\
J_3 &= -\frac{\sqrt{2\pi\nu_1}}{\nu_1^2 - \nu_2^2} \left((\nu_1 + \nu_2) K\left(\frac{\nu_1 - \nu_2}{2\nu_1}\right) - 2\nu_2 E\left(\frac{\nu_1 - \nu_2}{2\nu_1}\right) \right) \quad \text{where } \nu_1 = \frac{\kappa}{P} \text{ and } \nu_2 = \frac{\theta}{P} + \frac{\beta^2}{4}, \\
J_4 &= \frac{64\sigma_1\Gamma\left(\frac{5}{4}\right)^2\Gamma\left(\frac{9}{4}\right)^2{}_3F_2\left(\frac{1}{4}, \frac{5}{4}, \frac{9}{4}; \frac{1}{2}, \frac{7}{4}; \frac{\sigma_2^2}{4\sigma_1^2}\right) - 9\sigma_2\Gamma\left(\frac{3}{4}\right)^3\Gamma\left(\frac{11}{4}\right){}_3F_2\left(\frac{3}{4}, \frac{7}{4}, \frac{11}{4}; \frac{3}{2}, \frac{9}{4}; \frac{\sigma_2^2}{4\sigma_1^2}\right)}{15\sqrt{2\pi}\sigma_1^{\frac{3}{2}}} \quad \text{where } \sigma_1 = \frac{\kappa}{P} \text{ and } \sigma_2 = \frac{2\theta}{P} + \frac{\beta^2}{4}, \\
J_5 &= \frac{\sqrt{\frac{\pi\sigma_1}{2}}}{P((\sigma_1 + \sigma_2)^2 - \sigma_1^2)^2} \left[((\sigma_1 + \sigma_2)^2 + \sigma_1(4(\sigma_1 + \sigma_2) + 3\sigma_1))K\left(\frac{-\sigma_2}{2\sigma_1}\right) - 2((\sigma_1 + \sigma_2)^2 + 3\sigma_1^2)E\left(\frac{-\sigma_2}{2\sigma_1}\right) \right].
\end{aligned}$$

can be derived in closed-form as

$$P_{\text{appro}} \approx \frac{M_{d_{\min}}}{2} + \frac{\beta M_{d_{\min}}}{4\sqrt{\pi}} \sum_{t=1}^5 J_t \quad (18)$$

where J_t 's are given at the top of this page. Here, $K(\cdot)$ and $E(\cdot)$ are the complete elliptic integral of the first and the second kind, respectively, and ${}_3F_2(\cdot)$ is a generalized hypergeometric function [20]. They are available in computer software packages such as MATLAB and MATHEMATICA. We omit the detailed derivations due to the space limit.

IV. SINGLE-RELAY SELECTION IN A NETWORK WITH AN ARBITRARY NUMBER OF RELAYS

In this section, we consider a network with an arbitrary number of relays. Also, we consider the coherent power coefficient only for the following reasons. Firstly, simulation in Section VI shows that in two-way relay networks with two relays, the coherent power coefficient outperforms the non-coherent power coefficient. Secondly, for the two-way communications, the overhead cost to gain the instantaneous CSI f_j and g_j at r_j is low. The relay can gain reliable estimations with only one pilot signal from each user and no feedback is needed. Finally, numerical results in Section VI also show that the approximation $K_1(x) \approx \frac{1}{x}$, while works well for the coherent power coefficient case, results in a loose CDF approximation for the non-coherent power coefficient case and is inappropriate for the BLER approximation.

Assume that all relays have the same power, i.e., $Q_j = Q$, for $j = 1, \dots, R$. Therefore, the CDF of γ_i can be calculated as $F_{\gamma_i}(x) = [F_{\gamma_j}(x)]^R$. However, the BLER analysis is intractable with (16) because of the modified Bessel function. Instead, we use the approximation in (17). Thus, the BLER analysis in this selection is for the high transmit power regime. Its accuracy is justified by the simulation results in Section VI. This approximation also allows the diversity derivation. With (17), $F_{\gamma_i}(x)$ can be approximated as

$$F_{\gamma_i}(x) \approx \left(1 - e^{-\frac{\theta}{P}x} + \frac{x}{P}e^{-\frac{(\theta+\kappa)}{P}x}\right)^R, \quad x \geq 0. \quad (19)$$

Using multinomial series expansion, (19) can be re-written as

$$F_{\gamma_i}(x) \approx \sum_{\substack{n_1, n_2, n_3 \geq 0 \\ n_1 + n_2 + n_3 = R}} \frac{R!}{n_1!n_2!n_3!} \frac{(-1)^{n_2}}{P^{n_3}} x^{n_3} e^{-\frac{\psi}{P}x} \quad (20)$$

where $\psi = \theta(n_2 + n_3) + \kappa n_3$.

Block Error Rate: With the aid of (11) and (20), the BLER can be evaluated as

$$P_{\text{appro}} \approx \frac{M_{d_{\min}}\beta}{4\sqrt{\pi}} \sum_{\substack{n_1, n_2, n_3 \geq 0 \\ n_1 + n_2 + n_3 = R}} \frac{R!(-1)^{n_2}}{n_1!n_2!n_3!P^{n_3}} \frac{\Gamma(n_3 - \frac{1}{2})}{\left(\frac{\psi}{P} + \frac{\beta^2}{4}\right)^{n_3 - \frac{1}{2}}} \quad (21)$$

where $\Gamma(\cdot)$ is the Gamma function. Note that the BLER with $Q_i \neq Q_j$ ($i \neq j$) can be evaluated in the same way. However, it is difficult to give a general expression in a compact form.

Diversity Order: When $x \rightarrow 0$, we have $1 - e^{-x} \approx x$. Therefore, for large P , (19) can be written as

$$F_{\gamma_i}(x) \approx \frac{x^R}{P^R} \left(\theta + e^{-\frac{\theta+\kappa}{P}x}\right)^R. \quad (22)$$

Using the binomial expansion and (11), the BLER is approximated for large P as

$$P_{\text{appro}} \approx \left[\frac{M_{d_{\min}}\beta}{4\sqrt{\pi}} \sum_{m=0}^R \binom{R}{m} \frac{\theta^{R-m}\Gamma\left(R + \frac{1}{2}\right)}{\left(\frac{m(\theta+\kappa)}{P} + \frac{\beta^2}{4}\right)^{\left(R + \frac{1}{2}\right)}} \right] P^{-R} \quad (23)$$

where $\binom{R}{m} = \frac{R!}{m!(R-m)!}$. The diversity order is thus R which is the full diversity in a Rayleigh fading environment for a network with R relays.

The relay selection algorithm can be performed at either end user, who knows all channels. The user can find the index of the relay with the highest worst end-to-end SNR and feedback its index. $\log R$ feedback bits are needed. Other strategies that require less or no feedback are available, but is out of the scope of this paper and will be explored later.

V. MULTIPLE-RELAY SELECTION

In this section, we generalize the opportunistic relaying scheme from single-relay selection to multiple-relay selection, in other words, more than one relays are allowed to participate in the second-phase of the communication. For one-way relay networks, multiple-relay selection is proposed in [6] and it is shown to have a much better performance than single-relay selection with a small amount of cost on the overhead.

Consider the two-way relay network in Fig. 1. When more than one relays are allowed to cooperate, for the relay signals to be added coherently at the two end users, during the second phase of communication, each relay should, in addition to amplifying the information, incorporate a phase shift to cancel

the phases of its channels. The coefficient at the i th relay should be $\alpha_i e^{j\varphi_i}$, where $\varphi_i = -(\angle f_i + \angle g_i)$, and $\angle \vartheta$ denotes the phase of a complex value ϑ . Again, the coherent power coefficient in (5) is used. Assume that Relays i_1, \dots, i_k are chosen. Let $\mathcal{R} = \{i_1, \dots, i_k\}$, which is the set of indices of the selected relays. Each end user receives a superposition of the relay transmissions as follows:

$$\begin{aligned} y_{u_1} &= \sum_{i \in \mathcal{R}} \alpha_i \left[\sqrt{P} f_i^2 e^{j\varphi_i} s_1 + \sqrt{P} |f_i g_i| s_2 + f_i \tilde{v}_i \right] + w_1 \\ y_{u_2} &= \sum_{i \in \mathcal{R}} \alpha_i \left[\sqrt{P} g_i^2 e^{j\varphi_i} s_2 + \sqrt{P} |f_i g_i| s_1 + g_i \tilde{v}_i \right] + w_2 \end{aligned} \quad (24)$$

where $\tilde{v}_i = v_i e^{j\varphi_i}$. After canceling the self-interference, U_1 and U_2 get:

$$\begin{aligned} \tilde{y}_{u_1} &= \sqrt{P} \sum_{i \in \mathcal{R}} \alpha_i |f_i g_i| s_2 + \sum_{i \in \mathcal{R}} \alpha_i f_i \tilde{v}_i + w_1 \\ \tilde{y}_{u_2} &= \sqrt{P} \sum_{i \in \mathcal{R}} \alpha_i |f_i g_i| s_1 + \sum_{i \in \mathcal{R}} \alpha_i g_i \tilde{v}_i + w_2. \end{aligned} \quad (25)$$

The ML decoding rules of the two users are thus,

$$\begin{aligned} U_1 : \quad \hat{s}_2 &= \arg \min_{s \in \mathcal{S}} \left| \tilde{y}_{u_1} - \sqrt{P} \sum_{i \in \mathcal{R}} \alpha_i |f_i g_i| s \right| \\ U_2 : \quad \hat{s}_1 &= \arg \min_{s \in \mathcal{S}} \left| \tilde{y}_{u_2} - \sqrt{P} \sum_{i \in \mathcal{R}} \alpha_i |f_i g_i| s \right|. \end{aligned} \quad (26)$$

Note that the phase adjustment does not affect the statistical properties of the additive noise at the relay nodes, i.e., v_i and \tilde{v}_i have the same variance. Thus, the received SNRs at the two users when the relay subset \mathcal{R} is selected are

$$\begin{aligned} U_1 : \quad \gamma_{u_1, \mathcal{R}} &= \frac{P \left(\sum_{i \in \mathcal{R}} \alpha_i |f_i g_i| \right)^2}{1 + \sum_{i \in \mathcal{R}} \alpha_i^2 |f_i|^2} \\ U_2 : \quad \gamma_{u_2, \mathcal{R}} &= \frac{P \left(\sum_{i \in \mathcal{R}} \alpha_i |f_i g_i| \right)^2}{1 + \sum_{i \in \mathcal{R}} \alpha_i^2 |g_i|^2} \end{aligned} \quad (27)$$

respectively. Based on our relay selection criterion explained in Section II, the multiple-relay selection scheme is thus to find the subset of $\{1, 2, \dots, R\}$ that results in the maximum worse end-to-end SNR. In other words,

$$\mathcal{R} = \arg \max_{\mathcal{R} \subseteq \{1, 2, \dots, R\}} \min\{\gamma_{u_1, \mathcal{R}}, \gamma_{u_2, \mathcal{R}}\}.$$

As there are R relays and each relay has two choices, there are $2^R - 1$ possibilities (the case that no relay cooperates is obviously not optimal). One can always find the optimal solution by exhaustive search. But the computational complexity is exponential in R , and the number of required feedback bits is R since one bit for each relay is needed. For networks with large numbers of relays, having the amount of feedback bits linear in the network size is undesirable. Thus, the same as one-way relay networks, the real challenge of the problem is to find multiple-relay selection schemes with low complexity, good performance, and, at the same time, low feedback requirement. This motivates the relay ordering

idea in one-way networks [6]. With a relay ordering, one can find the cooperating relays sequentially. Although it is proved that for one-way relay networks, the optimal relay ordering does not exist, a relay ordering function based on the end-to-end SNR is proposed which is shown to achieve the full diversity and near optimal performance with linear or quadratic complexity. In this paper, we generalize the idea to two-way networks and propose the worse end-to-end SNR as the relay ordering function. The proposed multiple-relay selection scheme is described in Algorithm 1.

Algorithm 1 Multiple-relay selection algorithm for two-way networks.

- 1: Find $\gamma_j = \min(\gamma_{u_1, j}, \gamma_{u_2, j})$, using (7) for all $j = 1, \dots, R$.
 - 2: Sort γ_j , in descending order to get a relay ordering (i_1, \dots, i_R) .
 - 3: **for** $k = 1 : R$ **do**
 - 4: calculate $\gamma_{u_1, \{i_1, \dots, i_k\}}$ and $\gamma_{u_2, \{i_1, \dots, i_k\}}$ using (27).
 - 5: Find $\hat{k} = \arg \max_k \min(\gamma_{u_1, \{i_1, \dots, i_k\}}, \gamma_{u_2, \{i_1, \dots, i_k\}})$.
 - 6: Broadcast a number that is between $\min\{\gamma_{u_1, i_{\hat{k}}}, \gamma_{u_2, i_{\hat{k}}}\}$ and $\min\{\gamma_{u_1, i_{\hat{k}+1}}, \gamma_{u_2, i_{\hat{k}+1}}\}$.
-

The relay selection scheme can be conducted by either end user who knows all the channels. Relay j hears the value broadcasted by the end user and compares the value with its own worse end-to-end SNR, γ_j . If γ_j is larger, Relay j cooperates; otherwise, it does not cooperate. The scheme requires feedback of one positive number that is common to all relays. Thus, the required number of feedback bits is a fixed number whose value depends on the required precision. More efficient selection strategies may exist but is beyond the scope of this paper and will be explored later.

VI. NUMERICAL AND SIMULATION RESULTS

In this section, we give numerical and simulation results to verify our analysis, and to evaluate the performance of the relay selection schemes. QPSK is used as the modulation scheme in which $\beta = \sqrt{2}$ and $M_{d_{\min}} = 2$.

Since the exact analytical expressions for the CDFs of the worse end-to-end SNRs make the BLER analysis intractable, two approximations have been introduced, using the mean value theorem in Section III (referred to as *appro 1*) and using $K_1(x) \approx \frac{1}{x}$ for large x together with the mean value theorem in Section IV (referred to as *appro 2*). We justify the approximations by numerical results and simulation here. Fig. 2 compares the two approximations with its exact CDFs for both coherent and non-coherent cases when $P = Q = 10$ dB. The exact CDFs are generated by Monte-Carlo simulation. It shows that *appro 1* is very close to the exact one. Similar phenomenon can be observed for other values of P . Therefore, the approximation for the single-relay selection in a two-relay network with coherent or non-coherent power coefficient in Section III is precise for a large range of P and Q . However, *appro 2* is not as close to the exact one as *appro 1*, and the

Fig. 2. Comparison of CDFs.

Fig. 4. Single-relay selection with coherent power coefficient.

Fig. 3. Single-relay selection with coherent and non-coherent power coefficients.

Fig. 5. Multiple-relay selection with coherent power coefficient.

gap from the exact CDF is much larger in the non-coherent case than in the coherent case.

In Fig. 3, the BLERs of a two-way network with two relays under the proposed single-relay selection scheme are shown. The non-coherent power coefficient case is shown under two power scenarios: 1) $P = Q$ and 2) $P = 3Q$. The coherent power coefficient case is shown under three power scenarios: 1) $P = Q/5$, 2) $P = Q$, and 3) $P = 3Q$. For all cases, networks with coherent power coefficient outperform those with non-coherent power coefficient. To achieve 10^{-5} BLER, the coherent case is approximately 5 dB and 6 dB better when $P = Q$ and $P = 3Q$, respectively. With coherent power coefficient, the difference between $P = Q$ and $P = 3Q$ to achieve 10^{-5} BLER is 3.5 dB, while with non-coherent power coefficient, the difference is 5 dB. This means the coherent power coefficient case is less sensitive to the relay power fluctuation. The figure also shows that the analytical approximation is a tight lower bound on the BLER. For all

network scenarios, it approximates the BLER with less than 1/2 dB difference.

In Fig. 4, we consider relay networks with $R = 1, 2, 3, 4$ for $P = Q$ to see the diversity result. It shows clearly that the diversity gain changes from 1 to 4 when R varies from 1 to 4. This is consistent with our result that diversity R can be achieved. Further, the BLER approximation in (21) acts as a lower bound which is consistent with our discussion before, and it is a tight bound for large P . For each case of R , the gap between the simulation curve and the approximation curve is less than 0.3 dB at 10^{-6} BLER.

Fig. 5 shows BLER performance of multiple-relay selection scheme for $R = 2, 3$, and 4, where ‘RS’ stands for ‘relay selection’. For comparison, performance of single-relay selection is also given in Fig. 5. It shows that both schemes have the same diversity order R , but multiple-relay selection has a larger array gain. The array gain increases as the number of relays increases. To achieve 10^{-6} BLER, multiple-relay selection outperforms the single-relay selection by approximately 2 dB,

5 dB, and 7 dB for $R = 2$, $R = 3$, and $R = 4$, respectively.

VII. CONCLUSION

A two-way relay network with multiple AF relays is considered for both non-coherent and coherent power coefficients at the relays. A simple relay selection scheme which chooses the relay that results in the highest worst receive SNR of the two users is proposed. Then, a multiple-relay selection scheme is considered by ordering the set of relays in descending order of the worst receive SNR of the two users. The BLER approximation for single-relay selection in a two-relay network is shown to be accurate for any transmit power. The approximation used in single-relay selection with an arbitrary number of relays is shown to be accurate when the transmit power is high. It is also shown that a two-way relay network with coherent power coefficient outperforms that with non-coherent power coefficient. Both the single-relay selection and the multiple-relay selection schemes achieve full diversity, while the latter achieves a larger array gain than the former.

APPENDIX

Let $\alpha = |f_j|^2$ and $\zeta = |g_j|^2$, which have exponential distributions. For any $x > 0$, we define $b_j \triangleq \frac{x}{P}$ and $a_j \triangleq \frac{Q_j x + \sqrt{Q_j^2 x^2 + 4PQ_j(1+2P)x}}{2PQ_j}$. For $x \geq 0$, we have $0 \leq b_j \leq a_j$. Therefore, the probability of $\gamma_j \geq x$ can be given as

$$\begin{aligned} \mathbb{P}(\gamma_j \geq x) &= \int_0^{b_j} \mathbb{P}(\gamma_j \geq x | t = \alpha) e^{-t} dt \\ &+ \int_{b_j}^{a_j} \mathbb{P}(\gamma_j \geq x | t = \alpha) e^{-t} dt \\ &+ \int_{a_j}^{\infty} \mathbb{P}(\gamma_j \geq x | t = \alpha) e^{-t} dt. \end{aligned} \quad (28)$$

When $\alpha \in [0, b_j]$, we have

$$\begin{aligned} (P\alpha - x) < 0 < \frac{x(1+2P)}{\zeta Q_j} &\Rightarrow \frac{PQ_j \alpha \zeta}{1+2p + \zeta Q_j} < x \\ \Rightarrow \gamma_{u_1,j} < x &\Rightarrow \gamma_j < x. \end{aligned}$$

Thus, the first integral in (28) is zero. When $0 \leq b_j \leq \alpha$,

$$\begin{aligned} \gamma_{u_1,j} \geq x &\Leftrightarrow PQ_j \alpha \zeta \geq (Q_j \alpha + 2P + 1)x \\ \Leftrightarrow \zeta &\geq \frac{Q_j \alpha + (1+2P)x}{PQ_j \alpha} x \triangleq c_{1,j}. \end{aligned}$$

Similarly, $\gamma_{u_2,j} \geq x \Leftrightarrow \zeta \geq \frac{1+2P}{PQ_j \alpha - Q_j x} x \triangleq c_{2,j}$. Therefore,

$$\begin{aligned} \gamma_j \geq x &\Leftrightarrow \gamma_{u_1,j} > x, \\ \gamma_{u_2,j} > x &\Leftrightarrow \zeta \geq \max\{c_{1,j}, c_{2,j}\}, \\ c_{1,j} \geq c_{2,j} &\Leftrightarrow PQ_j \alpha^2 - Q_j x \alpha - x(1+2P) \geq 0, \\ PQ_j \alpha^2 - Q_j x \alpha - x(1+2P) = 0 &\Leftrightarrow \alpha = a_j. \end{aligned}$$

Since $a_j \geq b_j$, we can conclude that for $\alpha \geq b_j$,

$$c_{1,j} \geq c_{2,j} \Leftrightarrow \alpha \geq a_j.$$

Therefore, (28) can be re-written as

$$\mathbb{P}(\gamma_j \geq x) = \int_{b_j}^{a_j} e^{-c_{2,j}} e^{-t} dt + \int_{a_j}^{\infty} e^{-c_{1,j}} e^{-t} dt. \quad (29)$$

Using the definitions of $c_{1,j}$ and $c_{2,j}$ given above, (29) can be evaluated with the aid of the transformation $t - \frac{x}{P} = y$ and [20, eq. 3.324.1], to yield

$$\begin{aligned} \mathbb{P}(\gamma_j \geq x) &= \eta_j \sqrt{x} e^{-\frac{x}{P}} K_1(\eta_j \sqrt{x}) \\ &- e^{-\frac{x}{P}} \int_{a_j - \frac{x}{P}}^{a_j} e^{-\left(y + \frac{\eta_j^2 x}{4y}\right)} dy \end{aligned} \quad (30)$$

where $\eta_j = 2\sqrt{\frac{(1+2P)}{PQ_j}}$. The CDF of γ_j can be written as $F_{\gamma_j}(x) = \mathbb{P}(\gamma_j \leq x) = 1 - \mathbb{P}(\gamma_j \geq x)$, which proves (12).
