Unified Analysis of Low-SNR Energy Detection and Threshold Selection

Saman Atapattu, Member, IEEE, Chinthana Tellambura, Fellow, IEEE, Hai Jiang, Member, IEEE, and Nandana Rajatheva, Senior Member, IEEE

Abstract—For spectrum sensing in cognitive radio networks, the IEEE 802.22 standard requires the detection of primary signals with a signal-to-noise ratio (SNR) as low as -20 dB and receiver sensitivity as low as -116 dBm. Under such low-SNR levels, the performance of a conventional energy detector is analyzed in this paper. The analysis includes novel expressions for missed-detection probability and area under the receiver operating characteristic (ROC) curve. Thus, a unified framework covering fading channels, square-law diversity combining and cooperative spectrum-sensing scenarios is developed. The detection threshold is optimized to minimize the total error rate subject to bounded false alarm and missed-detection probabilities, which outperforms traditional detection threshold selection. Numerical results and Monte-Carlo simulation results with the IEEE 802.22 sensing requirements are provided and discussed.

Index Terms—Cognitive radio, energy detection, low-SNR, spectrum sensing, threshold selection.

I. INTRODUCTION

ROADBAND wireless access using the television (TV) white space spectrum has been approved by the US Federal Communications Commission (FCC). Among the standardization efforts [1], the IEEE 802.22 wireless regional area network (WRAN), which is designed to operate in the vacant TV bands, brings broadband access not only to the WiFi devices but also to general mobile networks (e.g., micro-cells, pico-cells, or femto-cells), allowing the use of the cognitive radio on a non-interfering basis [2]–[4].

However, cognitive radio requires spectrum sensing for opportunistic spectrum access. If spectrum sensing fails, primary users will have interference. For this reason, IEEE 802.22 prescribes the false alarm and missed-detection probabilities be less than 0.1. Due to possible multipath fading and/or shadowing caused by high-rise buildings, it is required that secondary users should reliably detect primary signals (i.e., satisfying the two requirements on false alarm and missed-detection probabilities) with a very low signal-to-noise ratio (SNR), such as -20 dB SNR with a signal power of -116 dBm and a noise floor of -96 dBm [4]. Thus, spectrum sensing at low SNR is vital.

Fortunately, a wide array of spectrum sensing techniques such as energy detection, matched filter detection, cyclostationary feature detection, covariance based detection and others may be employed [5]–[19]. While those techniques perform well at moderate and high SNRs, low-SNR operation typically requires a large number of samples, which impacts the sensing and processing time. For example, IEEE 802.22 limits the maximal detection latency to 2 seconds which may include sensing time and subsequent processing time. This maximal time limit is critical at low-SNR spectrum sensing.

Although spectrum sensing techniques at moderate and high SNRs have been researched a lot [5]–[9], the low-SNR case remains relatively unexplored. This case is treated for a differential energy detection scheme of multi-carrier systems (e.g., orthogonal frequency division multiplexing [OFDM]) in [10], for multi-antenna detectors (which improve the robustness to noise uncertainty) in [11], [12], and for a covariance based detection in [13]. Moreover, low-SNR cooperative spectrum sensing techniques are considered for belief propagation in [14], for cyclostationary detection in [15], for optimal relaying scheme in [16], and for multi-antenna with a noise-uncertainty-free detector in [17]. These works consider a generalized likelihood ratio (GLR) detector, an alternative energy detector, a cyclostationary feature detector, or a covariance based detector, in which the operating SNR ranges from -30 dB to 0 dB.

To complement those studies, we focus on energy detection, which has low complexity and low cost compared to other spectrum sensing techniques such as matched filter detection, cyclostationary feature detection, etc. [20]. Before that, we briefly mention some of the limitations of the state-of-the-art energy detection research when applied to the low-SNR case.

- Average detection (or missed-detection) probability derivation: In [21], the distribution of test statistic under each hypothesis follows a gamma distribution. Its cumulative distribution function (CDF) expression includes an incomplete gamma function. Only Gaussian channels are considered in [21]. With this model, the average detection probability under any fading channel has not been derived in closed-form in the literature (probably because of difficulties in further analysis with the incomplete gamma function). In [6]–[8], [22], by modeling the test statistic with its exact distribution, the aver-
age detection probabilities $P_d$ over fading channels are derived. These $P_d$ expressions however include special functions, infinite-order derivatives, and/or infinite series. Thus, computational complexity increases rapidly with $N$, the number of samples. In the low-SNR case, however, $N$ is several thousands, and thus, the resulting complexity is prohibitive. To reduce complexity, rather than using the exact distribution of the test statistic, an approximation can be used [21], [23]–[25]. But these works are limited to Gaussian channels. For the low-SNR energy detection, $P_d$ is derived for Rayleigh fading [26], and for Nakagami fading [27] with an integral form.

- Threshold selection: Traditionally, the threshold is selected to guarantee a given false alarm probability ($P_f$). For this purpose, the inversion of the $P_f$ expression is needed. Closed-form inversion however is not possible using results in [6]–[8], [21], [22]. This difficulty is heightened for IEEE 802.22 which additionally requires bounded missed-detection probability $P_{md}$ and bounded $P_f$ simultaneously. Although works in [28] and [29] perform Central Limit Theorem (CLT)-based threshold selection, they focus on non-fading scenarios only.

In summary, analytical tools specifically for low-SNR energy detector performance analysis and threshold selection over fading and/or shadowing channels may not be available.

**Contributions:** In this paper, we provide a rigorous unified performance analysis for conventional energy detection in the low-SNR regime. In particular, this paper makes the following contributions:

1) Missed-detection probability and Area Under receiver operating characteristic (ROC) Curve (AUC) for different fading and networking scenarios are derived, overcoming the aforementioned limitations (i.e., computational complexity).

2) Optimal threshold is formulated subject to bounded false-alarm and missed-detection probabilities. Approximate optimal threshold values are derived analytically.

3) Using the derived analytical results, numerical examples for the IEEE 802.22 requirements are presented. We show that these stringent low-SNR requirements can be achieved by sufficiently high number of samples and high sampling rate (MHz range). Moreover, cooperative sensing or diversity combining can help greatly.

The rest of this paper is organized as follows. Section II discusses energy detection, the system, low-SNR approximation, generalized SNR distribution, and the performance measures. Section III analyzes the missed-detection probability and AUC for low SNRs. Sections IV is devoted to the analysis of the optimal detection threshold. Section V presents numerical and simulation results, followed by concluding remarks in Section VI. Related proofs are provided in the Appendix. Some preliminary results of this paper have been presented in [30].

## II. ENERGY DETECTION PRELIMINARIES

Depending on whether the primary signal is present or not, the $n$th signal sample, $y(n) = \theta h s(n) + w(n)$ follows a binary hypothesis: $\mathcal{H}_0$ (signal absent, $\theta = 0$) and $\mathcal{H}_1$ (signal present, $\theta = 1$). Here, $h$, $s(n)$ and $w(n)$ denote the wireless channel gain, the $n$th primary signal sample and the $n$th additive white Gaussian noise (AWGN) sample, respectively. The test statistic is given as $\Lambda = \sum_{n=1}^{N} |y(n)|^2$, where $N$ is the number of samples. If the test statistic is larger than threshold $\lambda$, the primary signal is deemed to be present, and it is absent otherwise.

The AWGN samples $w(n)$, $n = 1, 2, \ldots, N$, are assumed to be independent and identically distributed (i.i.d.) circularly symmetric complex Gaussian (CSCG) random variables with mean zero and variance $\mathbb{E}[|w(n)|^2] = \sigma_w^2$, where $\mathbb{E}[]$ stands for expectation, i.e., $w(n) \sim \mathcal{CN}(0, \sigma_w^2)$. We assume that the detector knows the noise power exactly with the help of a noise power estimation technique [31]. Due to space limitation, we cannot treat the case with noise uncertainty in detail in this paper. However, a limited discussion can be found in Section V-D.

For i.i.d. signal samples under $\mathcal{H}_1$, the following three signal models are widely used in the literature:

- **S1:** $y(n)$ is Gaussian with nonzero mean, i.e., for given channel gain $h$, $\mathbb{E}[y(n)] = hs(n)$ [6], and the received SNR can be defined as
  \[
  \gamma_{S1} = \frac{|h|^2 N}{\sum_{n=1}^{N} |s(n)|^2}. \]

- **S2:** $s(n)$ is a CSCG random variable, $s(n) \sim \mathcal{CN}(0, \sigma_s^2)$, thus $y(n) \sim \mathcal{CN}(0, \sigma_s^2 + \sigma_w^2)$ [12], and the received SNR can be defined as $\gamma_{S2} = |h|^2 \sigma_s^2 / \sigma_w^2$.

- **S3:** $s(n)$ is a signal with zero mean and $\sigma_s^2$ variance (distribution may be unknown [13]), and thus, the received SNR is the same as $\gamma_{S2}$, i.e., $\gamma_{S3} = |h|^2 \sigma_s^2 / \sigma_w^2$.

For $S2$ and $S3$, with sufficiently large number of samples, the signal variance can be written by using its sample variance as

\[
\sigma_s^2 \approx \frac{1}{N} \sum_{n=1}^{N} |s(n)|^2 - \left( \frac{1}{N} \sum_{n=1}^{N} s(n) \right)^2.
\]

If the sample mean goes to zero, i.e., $[\sum_{n=1}^{N} s(n)]/N \rightarrow 0$, then $\sigma_s^2 \approx [\sum_{n=1}^{N} |s(n)|^2]/N$, and thus, the received SNRs under the three signal models are approximately equal, given as

\[
\frac{|h|^2}{\sigma_w^2} \sum_{n=1}^{N} |s(n)|^2.
\]

Thus, without loss of generality, we denote the SNR at the detector as $\gamma$ (i.e., $\gamma = \gamma_{S1}, \gamma_{S2}$, or $\gamma_{S3}$) for the rest of this paper.

The distribution of $\Lambda$ for given $h$ can be modeled exactly for all three signal models, but not for $S3$ under $\mathcal{H}_1$. Therefore, by using the CLT, the distribution of $\Lambda$ given $h$ can be approximated as a normal distribution for sufficiently large $N$ as [25]

\[
\Lambda | h \sim \left\{ \begin{array}{ll}
\mathcal{N} \left( N \sigma_w^2, N \sigma_w^2 \right) & : \mathcal{H}_0 \\
\mathcal{N} \left( N \sigma_w^2 (1 + \gamma), N \sigma_w^2 (1 + 2 \gamma) \right) & : \mathcal{H}_1 \text{ with } S1 \\
\mathcal{N} \left( N \sigma_w^2 (1 + \gamma), N \sigma_w^2 (1 + 2 \gamma)^2 \right) & : \mathcal{H}_1 \text{ with } S2.
\end{array} \right.
\]

\[
\Lambda | h \sim \left\{ \begin{array}{ll}
\mathcal{N} \left( N \sigma_w^2, N \sigma_w^2 \right) & : \mathcal{H}_0 \\
\mathcal{N} \left( N \sigma_w^2 (1 + \gamma), N \sigma_w^2 (1 + 2 \gamma) \right) & : \mathcal{H}_1 \text{ with } S1 \\
\mathcal{N} \left( N \sigma_w^2 (1 + \gamma), N \sigma_w^2 (1 + 2 \gamma)^2 \right) & : \mathcal{H}_1 \text{ with } S2.
\end{array} \right.
\]
The probability density function (PDF) of $\Lambda$ under $\mathcal{H}_0$, denoted $f_{\Lambda|\mathcal{H}_0}(x)$, and the PDF of $\Lambda$ under $\mathcal{H}_1$, denoted $f_{\Lambda|\mathcal{H}_1}(x)$, can be derived from (1). Under the low-SNR assumption ($\gamma \ll 1$), the signal has little impact on the variance of the test statistic under $\mathcal{H}_1$. Thus, in the low-SNR regime, expression (1) can be approximately approximated for any of the three signal models as [26], [31]

$$
\Lambda_{\text{low}} \approx \left\{ \begin{array}{ll}
\mathcal{N}(N\sigma_w^2, N\sigma_w^4) : & \mathcal{H}_0 \\
\mathcal{N}(N\sigma_w^2(1+\gamma), N\sigma_w^4) : & \mathcal{H}_1.
\end{array} \right.
$$

(2)

While the exact $P_f$ and $P_{\text{md}}$ expressions are different for the three different signal models ($S_1$, $S_2$, and $S_3$), the adoption of (2) permits a unified and accurate treatment for the three signal models, as follows. Thus, this approximation (2) is used for the rest of this paper.

Based on (2), the false alarm probability $P_f$ and the missed-detection probability $P_{\text{md}}(\gamma)$ can be evaluated as

$$
P_f = \frac{1}{2} \text{Erfc} \left( \frac{\lambda - N\sigma_w^2}{\sqrt{2N\sigma_w^2}} \right)
$$

(3)

and

$$
P_{\text{md}}(\gamma) \approx 1 - \frac{1}{2} \text{Erfc} \left( \frac{\lambda - N\sigma_w^2(1+\gamma)}{\sqrt{2N\sigma_w^2}} \right),
$$

(4)

respectively, where Erfc$(\cdot)$ is the complementary error function defined as Erfc$(z) = (2/\sqrt{\pi}) \int_z^{\infty} e^{-t^2} dt$.

Since $P_{\text{md}}(\gamma)$ depends on channel gain, a generalized SNR distribution is necessary to derive analytical results valid for various cases with path loss, large-scale fading and/or small-scale fading. Thus, we use a mixture of gamma distributions [33] for $\gamma$

$$
f_{\gamma}(x) = \sum_{i=1}^{S} \alpha_i x^{\beta_i-1} e^{-\zeta_i x}, \quad x \geq 0, \quad \alpha_i, \beta_i, \zeta_i > 0,
$$

(5)

where $S$ is the number of terms, $\alpha_i$, $\beta_i$ and $\zeta_i$ are parameters that represent the potential fading and shadowing effects, and $\sum_{i=1}^{S} \alpha_i \Gamma(\beta_i) e^{-\beta_i} = 1$, where $\Gamma(\cdot)$ is the gamma function. It is shown in [33] that the generalized SNR distribution (5) can accurately represent all existing fading/shadowing channels, diversity-combining techniques and cooperative spectrum-sensing networks.

III. Performance Analysis at a Low SNR

This section, by using (5), develops a unified analysis for the low-SNR regime: i) average missed-detection probability; and ii) average AUC. Diversity combining and cooperative spectrum sensing are also investigated subsequently.

A. Average Missed-Detection Probability

Given the AWGN expression (4), average missed-detection probability over fading channels, $P_{\text{md}}$, can be calculated by directly averaging over the SNR distribution to yield

$$
P_{\text{md}} = \frac{1}{2} \text{Erfc} \left( \frac{\lambda - N\sigma_w^2}{\sqrt{2N\sigma_w^2}} \right).
$$

(6)

(7)

With the aid of (4), (5), Erfc$(-x) = 2 - \text{Erfc}(x)$, and some straightforward algebraic manipulations, average missed-detection probability over the generalized SNR distribution (5), denoted $\mathcal{P}_{\text{md}}^\text{Gen}$, can be given as

$$
\mathcal{P}_{\text{md}}^\text{Gen} = \sum_{i=1}^{S} \alpha_i \mathcal{I}(\beta_i - 1, \zeta_i, \sqrt{\frac{N}{2}} \sqrt{\frac{N\sigma_w^2 - \lambda}{2N\sigma_w^2}}).
$$

(8)

where

$$
\mathcal{I}(n, p, c, d) \triangleq \int_{0}^{\infty} x^n e^{-px} \text{Erfc}(cx + d) dx = \left( -1 \right)^n \frac{\partial^n \psi(p)}{\partial p^n},
$$

(9)

Here, we define an integral expression, $\mathcal{I}(n, p, c, d)$, which will be used in subsequent analysis, as [34, eq. (2.8.9.1)]

$$
\mathcal{I}(n, p, c, d) \triangleq \int_{0}^{\infty} x^n e^{-px} \text{Erfc}(cx + d) dx = \left( -1 \right)^n \frac{\partial^n \psi(p)}{\partial p^n},
$$

(10)

This novel closed-form expression has a low computational complexity because of the following reasons.

In (9), we need $(\beta_i - 1)$th partial derivative (with respect to $p$) of $\psi(p)$ with

$$
c = \sqrt{\frac{N}{2}}, \quad d = \frac{N\sigma_w^2 - \lambda}{2N\sigma_w^2},
$$

and $\beta_i$ can take values $\beta_1, \cdots, \beta_S$. For fading channels, diversity or cooperative networks, $\beta_i$ value may be a fading parameter, the number of diversity branches, or the number of cooperative nodes, which are small integer values. Further, values of $\beta_i$ and $S$ are typically small. Since $\psi(p)$ includes only exponential and Erfc$(\cdot)$ functions of $p$, its derivatives are also closed-form expressions for given $\beta_i$ and $S$, including only exponential and Erfc$(\cdot)$ functions of $p$. The particular expressions are omitted for brevity. The most important fact is that the computational complexity of (9) does not increase with $N$ (noting that the value of $N$ is typically several thousands in the low-SNR regime). In contrast to (7), the complexity of other existing $P_{\text{md}}$ expressions in the literature increases with $N$, for example:

- Confluent Hypergeometric functions and Laguerre polynomials [6], and generalized Hypergeometric functions [7] need infinite number of steps.
- The order of derivative equals the number of samples $N$ for residue calculations, and subsequently infinite series are used in the calculation [8], or infinite-order derivatives are required [22].

Therefore, (7) is especially suited for the low-SNR regime, e.g., as used in the threshold selection analysis in Section IV.

Now we consider special cases of (7). For Rayleigh fading, the parameters are $S = 1$, $\alpha_1 = 1/\bar{\gamma}$ ($\bar{\gamma}$ is average SNR),
Thus, the average missed-detection probability \( P_{\text{md}}^{\text{Ray}} \) is given as
\[
\frac{1}{2} \left[ \text{Erfc} \left( \frac{N \sigma_n^2 - \lambda}{\sqrt{2N \sigma_w^2}} \right) - e^{-\frac{1}{2} \left( \frac{N \sigma_n^2 - \lambda}{\sqrt{2N \sigma_w^2}} \right)^2} \right] \times \text{Erfc} \left( \frac{N \sigma_n^2 - \lambda}{\sqrt{2N \sigma_w^2}} + \frac{1}{\gamma \sqrt{2N}} \right).
\]
(8)

For a Nakagami-\( m \) fading channel, the parameters are
\[ S = 1, \quad \alpha_1 = \frac{m}{\Gamma(m) \gamma^m}, \quad \beta_1 = m, \quad \zeta_1 = \frac{m}{\gamma}, \]
and the missed-detection probability, \( P_{\text{md}}^{\text{Nak}} \), is
\[
\frac{1}{2 \Gamma(m)} \left( \frac{m}{\gamma} \right)^m I \left( m - 1, m \gamma \sqrt{\frac{N}{2} \left( N \sigma_n^2 - \lambda \right)} \right).
\]
(9)

Similarly, the average missed-detection probabilities over many other existing fading channels (not only multipath fading channels) such as Nakagami-lognormal, \( K \), \( K_G \), \( \eta \)-\( \mu \), Nakagami-\( q \) (Hoyt), \( \kappa \)-\( \mu \), or Nakagami-\( n \) (Rician) can be derived easily after properly selecting the parameters \( S \), \( \alpha_i \), \( \beta_i \), \( \zeta_i \) (\( i = 1, 2, \ldots, S \)).

For the square-law combining (SLC) with a low SNR, the false alarm probability and the missed-detection probability under AWGN channels can be evaluated as (3) and (4), respectively, with \( N \) replaced by \( LN \) (here \( L \) is the number of diversity branches). For fading channels, denote the SNR over the branches as \( \gamma_1, \gamma_2, \ldots, \gamma_L \). If the PDF of \( \gamma = \left[ \sum_{i=1}^{L} \gamma_i \right] / L \) is modeled by using the generalized channel (5),
\(^1\) with the aid of (7), the average missed-detection probability can be derived as
\[
\frac{1}{2 \Gamma(L)} \left( \frac{L}{\gamma} \right)^L \sum_{i=1}^{S} \alpha_i I \left( \beta_i - 1, \zeta_i, \sqrt{\frac{LN}{2} N \sigma_w^2 - \lambda} \right).
\]
(10)

Thus, the average missed-detection probability over a Rayleigh fading channel can be derived by using (10) with \( S = 1, \)
\[
\alpha_1 = \frac{1}{\Gamma(L)} \left( \frac{L}{\gamma} \right)^L,
\]
\[ \beta_1 = L \text{ and } \zeta_1 = L / \bar{\gamma}. \]
Similarly, the average missed-detection probability over a Nakagami-\( m \) fading channel can be derived by using (10) with \( S = 1, \)
\[
\alpha_1 = \frac{1}{\Gamma(mL)} \left( \frac{mL}{\gamma} \right)^{mL},
\]
\[ \beta_1 = mL \text{ and } \zeta_1 = mL / \bar{\gamma}. \]

As special cases, the PDF of \( \gamma = \left[ \sum_{i=1}^{L} \gamma_i \right] / L \) when signals of the branches follow i.i.d. Rayleigh and Nakagami-m fading are
\[
f_\gamma(x) = \frac{1}{\Gamma(L)} \left( \frac{L}{\gamma} \right)^L x^{L-1} e^{-\frac{x}{\gamma}},
\]
\[
f_\gamma(x) = \frac{1}{\Gamma(mL)} \left( \frac{mL}{\gamma} \right)^{mL} x^{mL-1} e^{-\frac{x}{\gamma}},
\]
respectively, where \( \bar{\gamma} \) is the average SNR at each branch [6].

If there are \( K \) cooperative nodes, each of which sends to a fusion center its own decision on presence/absence of the primary signal, and the fusion center uses the \( k \)-out-of-\( K \) fusion rule, the false alarm probability \( p_f^{\text{coop}} \) and detection probability \( p_d^{\text{coop}} \) at the fusion center can be written as
\[
p_f^{\text{coop}} = \sum_{i=k}^{K} \left( \frac{K}{i} \right) \left( 1 - p_f \right)^{K-i} (p_f)^i,
\]
where the notation ‘‘\( K \)’’ means ‘‘\( f \)’’ for false alarm and means ‘‘\( d \)’’ for detection. Here, the channels from the primary user to the cooperative nodes are assumed to be i.i.d., and thus, all the cooperative nodes can achieve identical false alarm probability \( p_f \) and detection probability \( p_d \). Thus, the average missed-detection probability of cooperative spectrum sensing is
\[
P_{\text{md}}^{\text{Gen}, \text{Coop}} \approx 1 - \sum_{i=k}^{K} \left( \frac{K}{i} \right) \left( \frac{p_f}{1 - p_d} \right)^i \left( 1 - p_d \right)^i,
\]
with \( P_{\text{md}}^{\text{Gen}} \) given in (7).

B. Average Area under ROC Curve (AUC)

The ROC curve is the plot of \( P_d \) versus \( P_f \) as threshold \( \lambda \) varies from 0 to \( \infty \). By eliminating the variable \( \lambda \), \( P_d \) can be expressed as function of \( P_f \). The area under the ROC curve is the AUC, which varies between 0.5 and 1. It represents the probability that the detector is more likely to choose the correct decision than the incorrect decision [35]. In Theorem 1, we derive a general expression for the AUC for AWGN channels.

**Theorem 1.** Define
\[
P_f(\lambda) = \frac{1}{2} \text{Erfc} \left( \frac{\lambda - m_0}{\sqrt{2} \sigma_0} \right), \quad P_d(\lambda) = \frac{1}{2} \text{Erfc} \left( \frac{\lambda - m_1}{\sqrt{2} \sigma_1} \right),
\]
which are functions of \( \lambda \) \((-\infty < \lambda < \infty)\),\(^2\) where \( m_0, m_1, \sigma_0, \) and \( \sigma_1 \) are real positive values such that \( m_0 \leq m_1 \) and \( \sigma_0 \leq \sigma_1 \). By eliminating term \( \lambda \), the two functions can be combined as
\[
P_d = \frac{1}{2} \text{Erfc} \left( \frac{\sigma_0}{\sigma_1} \text{Erfc}^{-1}(2P_f) - \frac{m_1 - m_0}{\sqrt{2} \sigma_1} \right),
\]
which represents the \( P_d \) versus \( P_f \) curve. Thus, the area under the \( P_d \) versus \( P_f \) curve, \( A \), is given as
\[
A = 1 - \frac{1}{2} \text{Erfc} \left( \frac{m_1 - m_0}{\sqrt{2(\sigma_0^2 + \sigma_1^2)}} \right).
\]
(12)

**Proof:** See Appendix A.

The instantaneous AUC of an energy detector at a low SNR can be derived from (12) by replacing \( m_0 = N \sigma_w^2, m_1 = N \sigma_w^2(1 + \gamma), \sigma_0^2 = N \sigma_w^4, \) and \( \sigma_1^2 = N \sigma_w^4, \) as
\[
A(\gamma) \approx 1 - \frac{1}{2} \text{Erfc} \left( \frac{\sqrt{N}}{2} \gamma \right).
\]

\(^2\)This is the theoretical limit of \( \lambda \). But negative values of the threshold \( \lambda \) are not considered in practice.
Now we derive the average AUC over the generalized SNR distribution (5) as $\mathcal{A}_{\text{gen}}^\text{avg} = \int_0^\infty A(x) f_\gamma(x) \, dx$, to yield

$$\mathcal{A}_{\text{gen}}^\text{avg} \approx 1 - \frac{1}{2} \sum_{i=1}^S \alpha_i \int_0^\infty x^{\beta_i - 1} e^{-\zeta_i x} \text{Erfc} \left( \frac{\sqrt{N}}{2} x \right) \, dx$$

$$= 1 + \frac{1}{2} \sum_{i=1}^S (1 - \beta_i - \alpha_i) \times \frac{\partial^{i-1}}{\partial p^{i-1}} \left( \frac{1}{p} - \frac{1}{p} \right) \bigg|_{p = \frac{1}{\sqrt{N}}}$$

$$\approx \frac{1}{2} + \frac{e^{\gamma N^2/2} \text{Erfc} \left( 1/\sqrt{N} \right)}{1/\sqrt{N}}$$

where $\beta_i$ is a positive integer, and the equality in the second line of (13) comes after applying [34, eq. (2.8.5.4)]. This approximation can be used for many wireless channel models. For example, the average AUC over a Rayleigh fading channel, $\mathcal{A}_{\text{Ray}}^\text{avg}$, is

$$\mathcal{A}_{\text{Ray}}^\text{avg} \approx \frac{1}{2} + \frac{e^{\gamma N^2/2} \text{Erfc} \left( 1/\sqrt{N} \right)}{1/\sqrt{N}}$$

and the average AUC over a Nakagami-m fading channel, $\mathcal{A}_{\text{Nak}}^\text{avg}$, is

$$\mathcal{A}_{\text{Nak}}^\text{avg} \approx 1 + \frac{(-1)^{m-1}m^m}{2\Gamma(m)\gamma^m} \times \frac{\partial^{m-1}}{\partial p^{m-1}} \left( \frac{1}{p} - \frac{1}{p} \right) \bigg|_{p = \frac{1}{\sqrt{N}}}$$

where $m$ is an integer.

Similarly, for the SLC technique, the AUC over Nakagami-m fading channels can be derived by using (13) with $S = 1$, $\alpha_1 = \frac{1}{\Gamma(mL)} \left( \frac{mL}{\gamma} \right)^m$, $\beta_1 = mL$, $\zeta_1 = mL$, and with $N$ replaced by $LN$. For cooperative spectrum sensing, because $P_{d}^{\text{coop}}$ is not expressible in terms of $P_{f}^{\text{coop}}$, the AUC can be expressed as an integral only, which can be evaluated by numerical methods. However, a closed-form expression appears intractable.

IV. THRESHOLD SELECTION

Threshold selection is traditionally based on the false alarm probability only, which, unfortunately, does not work for cognitive radio networks where missed-detection results in interference on primary users. While threshold selection with different objective functions (by relaxing some constraints) has been performed in [28], [29] and many others, these papers focus on non-fading scenarios, or do not consider both $P_{\text{md}}(\lambda)$ and $P_f(\lambda)$ simultaneously.

For a cognitive radio network, $P_{\text{md}}(\lambda)$ and $P_f(\lambda)$ must be below the thresholds denoted $P_{\text{th}}^{\text{md}}$ and $P_{\text{th}}^{\text{f}}$. Since $P_{\text{md}}(\lambda)$ increases and $P_f(\lambda)$ decreases with threshold $\lambda$, these requirements are equivalent to $\lambda \leq \lambda^*_\text{md}$ and $\lambda \geq \lambda^*_f$ where $P_{\text{md}}(\lambda^*_\text{md}) = P_{\text{th}}^{\text{md}}$ and $P_f(\lambda^*_f) = P_{\text{th}}^{\text{f}}$.

If $\lambda^*_f > \lambda^*_\text{md}$, then there is no feasible $\lambda$ that satisfies both false-alarm and missed-detection requirements, which necessitates other remedial actions, such as increasing the sampling rate. If $\lambda^*_f \leq \lambda^*_\text{md}$, any $\lambda$ value within range $[\lambda^*_f, \lambda^*_\text{md}]$ can satisfy both false-alarm and missed-detection constraints. In this range, optimal $\lambda$ is then selected by optimizing a combination metric of both $P_{\text{f}}(\lambda)$ and $P_{\text{md}}(\lambda)$. For this purpose, the Bayesian cost [36], a popular metric to select the detection threshold [37]–[41], can be used. Minimizing the Bayesian cost is equivalent to minimizing the total error rate $P_e(\lambda) \triangleq P_f(\lambda) + P_{\text{md}}(\lambda)$. Therefore, the threshold selection problem is formulated as

$$\min_{\lambda} \quad P_f(\lambda) = P_f(\lambda) + P_{\text{md}}(\lambda)$$

subject to

$$P_f(\lambda) \leq P_{\text{th}}^{\text{f}}, \quad P_{\text{md}}(\lambda) \leq P_{\text{th}}^{\text{md}}.$$

We first relax the two constraints in (16), and denote the optimal solution as $\lambda^*_f$. Then the optimal solution for problem (16), denoted $\lambda^*$, is given as

$$\lambda^* = \begin{cases} \lambda^*_f : & \text{if } \lambda^*_f \leq \lambda^*_\text{md} \text{ and } \lambda^*_f \in [\lambda^*_f, \lambda^*_\text{md}], \\ \lambda^*_f \text{ or } \lambda^*_\text{md} : & \text{whichever is closer to } \lambda^*_e : \text{if } \lambda^*_f \leq \lambda^*_\text{md} \text{ and } \lambda^*_e \notin [\lambda^*_f, \lambda^*_\text{md}], \\ \text{no solution} : & \text{if } \lambda^*_f > \lambda^*_\text{md}. \end{cases}$$

Since $P_f(\lambda)$ does not depend on fading effect, $\lambda^*_f$ can be derived regardless of any fading scenario by using (3) as

$$\lambda^*_f = \left( \frac{2}{N} \text{Erfc}^{-1} \left( 2P_{\text{th}}^{\text{f}} \right) + 1 \right) N\sigma^2_w.$$

In the following, we derive exact $\lambda^*_\text{md}$ and $\lambda^*_e$ for AWGN channels and approximate them for multipath fading channels. Generally, for any fading model (Gaussian, Rayleigh, etc.), minimum $P_e(\lambda)$ is achieved when $\frac{\partial P_e(\lambda)}{\partial \lambda} = 0$, which is illustrated in Appendix B.

A. AWGN Channel

In this case, rather than using the low-SNR model in (2), we consider the general SNR case in (1), which leads to closed-form expressions of $\lambda^*_\text{md}$ and $\lambda^*_e$, as follows.\(^3\) For S1 or S3 signal model with any SNR value $\gamma$, $\lambda^*_\text{md}$ can be derived by using (1) as

$$\lambda^*_\text{md} = \left( \frac{2(1 + 2\gamma)}{N} \text{Erfc}^{-1} \left( 2(1 - P_{\text{th}}^{\text{md}}) \right) + 1 \right) N\sigma^2_w,$$

and $\lambda^*_e$ is given by using (1) as

$$\lambda^*_e = \arg \min_{\lambda} \frac{1}{2} \text{Erfc} \left( \frac{\lambda - N\sigma^2_w}{\sqrt{2N}\sigma^2_w} \right) - \frac{1}{2\sigma^2_w} \left( \frac{\lambda - N\sigma^2_w (1 + \gamma)}{\sqrt{2N(1 + 2\gamma)\sigma^2_w}} \right)^2$$

$$= \frac{N\sigma^2_w}{2} \left( 1 + \sqrt{1 + 2\gamma \left( 1 + \frac{(1 + 2\gamma) \ln(1 + 2\gamma)}{N\gamma^2} \right)} \right),$$

\(^3\)This implies that the derived (18), (19), and (20) are valid from low to high SNR.
where the second equality comes as explained in Appendix C. Similarly, \( \lambda^*_{\text{nd}} \) and \( \lambda^*_e \) for S2 signal model can be derived as

\[
\lambda^*_{\text{nd}} = \left( \sqrt{\frac{2}{N}} (1 + \gamma) \text{Erfc}^{-1} \left( 2(1 - P_{\text{nd}}^m) \right) + (1 + \gamma) \right) N \sigma_w^2,
\]

\[
\lambda^*_e = \frac{N \sigma_w^2}{2} \left( 1 + \sqrt{1 + \frac{2(2 + \gamma) \ln(1 + \gamma)}{N \gamma}} \left( \frac{1 + \gamma}{1 + \frac{2}{N}} \right) \right).
\]  

(20)

### B. Multipath Fading

In Rayleigh and Nakagami-\( m \) fading in the low-SNR regime, the exact closed-form \( \lambda^*_{\text{nd}} \) and \( \lambda^*_e \) are intractable from missed-detection probabilities (8) and (9), although numerical computation is feasible. As a result, we derive approximations for Rayleigh and Nakagami-2 fading channels. Our procedure can also be extended for arbitrary \( m \geq 2 \). The approximations and simulations are compared in Table II in Section V, showing a close match.

1) Rayleigh Fading Channel: We define

\[
\alpha \triangleq \frac{N \sigma_w^2 - \lambda}{\sqrt{2N} \sigma_w^2}, \quad \alpha \triangleq \frac{1}{\sqrt{2N} \gamma},
\]

which will be used in this section. By using (8), \( P_{\text{md}}^\text{Ray} (\lambda) \) can be written as

\[
P_{\text{md}}^\text{Ray} (\lambda) \approx \frac{1}{2} \left[ \text{Erfc} (\alpha) - e^{\alpha^2} e^{2\alpha^2} \text{Erfc} (\alpha + \alpha) \right].
\]  

(21)

Thus, an approximate \( \lambda^*_{\text{md}} \) can be calculated as (22) on the next page, where \( u = ae^{\alpha^2} \text{Erfc}(a) \). The derivation is given in Appendix D1.

The total error rate is \( P_e (\lambda) = P_f (\lambda) + P_{\text{md}}^\text{Ray} (\lambda) \). For minimum \( P_e (\lambda) \), an approximate threshold can be given as

\[
\lambda^*_e \approx \left( 1 + \frac{1}{N \gamma} \sqrt{\frac{2}{N} \pi} + \frac{2}{N} \left( 1 - \sqrt{2N \gamma} \right) \right) N \sigma_w^2.
\]  

(23)

The derivation is given in Appendix D2.

2) Nakagami-2 Fading Channel: By using (9), \( P_{\text{md}}^\text{Nak} (\lambda) \) for Nakagami-2 fading channel can be written as

\[
P_{\text{md}}^\text{Nak} (\lambda) \approx \frac{1}{2} \text{Erfc} (\alpha) - \frac{2a}{\sqrt{\pi}} e^{-a^2} + \left( 4a^2 - \frac{1}{2} + 2\alpha a \right) e^{4a^2} e^{4a^2} \text{Erfc}(2a + \alpha).
\]  

(24)

Thus, \( \lambda^*_{\text{md}} \) can be calculated as (25) on next page, where \( v = a^2 e^{4a^2} \text{Erfc}(2a) \). The derivation is given in Appendix E1.

The total error rate is \( P_e (\lambda) = P_f (\lambda) + P_{\text{md}}^\text{Nak} (\lambda) \). For minimum \( P_e (\lambda) \), an approximate threshold can be given as

\[
\lambda^*_e \approx \frac{1}{2} \sqrt{\frac{\pi - \sqrt{\pi} - 8 + 2N \gamma^2}{2N \gamma}} N \sigma_w^2.
\]  

(26)

The derivation is given in Appendix E2.

3) Nakagami-\( m \) Fading Channel: For a given fading parameter \( m \), \( P_{\text{md}}^\text{Nak} \) can be derived in closed-form by using (9), which includes only exponential and \( \text{Erfc}(\cdot) \) functions. Following the similar procedure given in Section IV-B2, approximate \( \lambda^*_{\text{md}} \) and \( \lambda^*_e \) for a general Nakagami-\( m \) fading channel can easily be derived analytically. Moreover, by keeping increasing the number of terms of Taylor series expansions (e.g., polynomial with degree greater than 2), we can find more accurate approximations for \( \lambda^*_{\text{md}} \) and \( \lambda^*_e \).

### C. Diversity Combining or Cooperative Spectrum Sensing

If SLC is used, the results in Section IV-A can be applied with \( N \) replaced by \( LN \) for SLC over AWGN in which \( \gamma = [\sum_{i=1}^{L} \gamma_i] / L \), and numerical methods can be used for other fading channels by using (10). Similarly, if cooperative sensing is used, the optimal threshold can be determined by numerical methods by using (11).

### V. NUMERICAL/SIMULATION RESULTS AND DISCUSSION

This section provides numerical results based on our preceding analysis, and semi-analytical Monte-Carlo simulation results based on the system model in Section II. Because all signal models perform more or less the same at low SNR, simulation is limited to S1 signal model only.

The normalized threshold is defined as \( \lambda = \lambda/N \). The noise variance is set to \( \sigma_w^2 = 1 \). For SLC and cooperative spectrum sensing, only Rayleigh fading is considered. The Rayleigh fading case provides a worst-case benchmark because its performance is much worse than those of AWGN and Nakagami-\( m \) (\( m > 1 \)) fading channels.

### A. Accuracy of our low-SNR missed-detection probability expressions

The ROC curves are calculated from (4), (8)-(11), and simulated (Figs. 1 and 2). Specifically, Fig. 1 shows the ROC curves for AWGN, Rayleigh and Nakagami-4 fading channels with -20 dB average SNR. The ROC curves are plotted in the range \( \lambda \in [0.95, 1.05] \) and \( \lambda \in [0.995, 1.02] \) for \( N = 2 \times 10^3 \) and \( N = 2 \times 10^5 \), respectively. Fig. 2 shows the ROC curves of SLC with \( L = 2, 3 \) and cooperative spectrum sensing (with OR decision fusion rule) with \( K = 2, 3 \) over Rayleigh fading at \( \gamma = -20 \text{dB} \) when \( N \) takes two values: when \( N = 2 \times 10^3 \), the ROC curves are plotted in the range \( \lambda \in [1.92, 2.10] \) and \( \lambda \in [2.94, 3.10] \) for SLC with \( L = 2 \) and 3, respectively, and in the range \( \lambda \in [0.95, 1.1] \) for cooperative spectrum sensing; when \( N = 2 \times 10^5 \), the ROC curves are plotted in the range \( \lambda \in [2.00, 2.02] \) and \( \lambda \in [3.00, 3.03] \) for SLC with \( L = 2 \) and 3, respectively, and in the range \( \lambda \in [0.99, 1.03] \) for cooperative spectrum sensing. The analytical results perfectly match the simulation results for a high and low number of samples, and also for high and low \( P_d \) and \( P_f \), confirming the accuracy of our low-SNR approximations in (4), (8)-(11). These figures show that when \( N = 2 \times 10^3 \), the IEEE 802.22 requirements on false alarm and missed-detection probabilities

\[ \text{This is the threshold if the decision statistic is selected as } \Lambda = \left[ \sum_{m=1}^{N} |y(n)|^2 \right] / N. \]
\[
\lambda_{md}^* \approx 1 - \sqrt{\frac{\lambda}{\pi}} \left( \sqrt{\pi u - \pi^{1/4} \left( \frac{4P_{md}^\text{th} u - 2a - u (2a(2P_{md}^\text{th} - 1)\sqrt{\pi} + \sqrt{\pi u - 2})}{2a(1 - \sqrt{\pi u})} \right)} \right) \quad N\sigma_w^2
\] (22)

\[
\lambda_{md}^* \approx 1 - \frac{4a^2 - 8\sqrt{\pi a v - \sqrt{\pi}} (2P_{md}^\text{th} - 1) (1 + 8a^2) - (32a^2 - a^2) v - 8a^4 + 4\sqrt{\pi} a^2 (a - 2P_{md}^\text{th} a + 8a^2 v))}{4(\sqrt{\pi} (1 + 8a^2) v - 4a^4)} \quad N\sigma_w^2
\] (25)

Fig. 1: Approximate (low-SNR analysis) ROC curves (solid lines) and simulated ROC curves (discrete marks) of AWGN, Rayleigh and Nakagami-4 fading channels for \( N = 2 \times 10^3 \) and \( N = 2 \times 10^5 \) at -20 dB SNR.

Fig. 2: Approximate (low-SNR analysis) ROC curves (solid lines) and simulated ROC curves (discrete marks) of SLC when \( L = 2, 3 \) and cooperative spectrum sensing when \( K = 2,3 \) for \( N = 2 \times 10^3 \) and \( N = 2 \times 10^6 \) over Rayleigh fading at -20 dB SNR.

cannot be satisfied simultaneously in any case in the two figures; when \( N = 2 \times 10^5 \), the requirements can be satisfied simultaneously for all cases in Fig. 1 except Rayleigh fading case; when \( N = 2 \times 10^6 \), the requirements can be satisfied simultaneously for all cases in Fig. 2. Thus, the impact of using more samples, more diversity branches or more cooperative nodes is clearly positive.

**B. Low-SNR AUC approximations**

By using eqs. (14) and (15), Table I lists results for three channels and SLC. Our approximations match closely with the simulations. As expected, AUCs for AWGN and Rayleigh cases vary from the largest to the smallest. With SLC, a larger number of branches leads to a higher AUC and provides better overall detection capability. Obviously, a larger number of samples also leads to a higher AUC confirming a better overall detection capability.

**C. Threshold selection**

The optimal threshold, \( \lambda^* \), is determined by minimizing the total error rate as in (16). We denote \( P_e^* = P_e(\lambda^*) \), \( P_f^* = P_f(\lambda^*) \), and \( P_{md}^* = P_{md}(\lambda^*) \). When \( \gamma = -20 \text{ dB} \) and \( N = 2 \times 10^6 \), Fig. 3 and Fig. 4 show low-SNR approximate total error rates (analytical results represented by solid lines, where the average missed-detection probability is calculated based on our analysis in Section III-A) and simulated total error rates (represented by discrete marks) versus the normalized threshold for the AWGN, Rayleigh, Nakagami-2 fading channels, cooperative spectrum sensing (\( K = 2 \)), and SLC diversity combining (\( L = 3 \)). Since the analytical results perfectly match the simulation results in Figs. 3 and 4, Table II shows only the numerically calculated normalized threshold values \( \lambda_f^*, \lambda_{md}^*, \lambda_r^*, \lambda_e^* \) (\( \lambda_f^* \) and \( \lambda_{md}^* \) are calculated under constraints \( P_f(\lambda) \leq 0.1 \) and \( P_{md}(\lambda) \leq 0.1 \), respectively), and numerically calculated false alarm probability, missed-detection probability, and total error rate at \( \lambda_e^* \). In Table II, the numbers in brackets are approximated \( \lambda_{md}^* \) and \( \lambda_r^* \) for Rayleigh fading channels based on (22) and (23) and for Nakagami-2 fading channels based on (25) and (26). From Table II, we have \( \lambda_f^* < \lambda_e^* < \lambda_{md}^* \) for AWGN channel, Nakagami-2 channel, SLC diversity combining, and cooperative sensing, and thus, \( \lambda_e^* = \lambda_r^* \). However, for Rayleigh

\( ^5 \) For AWGN channels, we have exact analytical solution for \( \lambda_{md}^* \) and \( \lambda_r^* \) as given in (18) and (19). For SLC or cooperative sensing over fading channels, we do not have analytical results for \( \lambda_{md}^* \) and \( \lambda_r^* \).
TABLE I: AUC approximations and simulated values (in the brackets) for AWGN, Rayleigh, Nakagami-4 channels in Fig. 1 and SLC (L = 2, 3) in Fig. 2.

TABLE II: Normalized threshold values \((\lambda_f^*, \lambda_{md}^*, \lambda_e^*, \lambda_e^*)\) and error probabilities \((P_f, P_{md}, P_e)\) at \(\lambda_f^*\) for AWGN, Rayleigh and Nakagami-2 channels, SLC, and cooperative spectrum sensing when \(N = 2 \times 10^6\) and \(\tilde{\gamma} = -20\) dB. The numbers in brackets are approximated \(\lambda_{md}^*\) and \(\lambda_e^*\) based on (22) and (23) for Rayleigh fading channels and based on (25) and (26) for Nakagami-2 fading channels, respectively. \(\lambda_f^*\) and \(\lambda_{md}^*\) are calculated under constraints \(P_f(\lambda) \leq 0.1\) and \(P_{md}(\lambda) \leq 0.1\), respectively.

![Fig. 3: Approximate total error rate (solid lines) and simulated total error rate (discrete marks) versus normalized threshold in AWGN, Rayleigh and Nakagami-2 channels and cooperative spectrum sensing (K = 2) over Rayleigh fading.](image1)

![Fig. 4: Approximate total error rate (solid lines) and simulated total error rate (discrete marks) versus normalized threshold in SLC (L = 3) over Rayleigh fading, for \(N = 2 \times 10^6\) at -20 dB average SNR.](image2)

Next we focus on the IEEE 802.22 requirements for spectrum sensing by using standard parameter values. These requirements specify that \(P_f \leq 0.1\) and \(P_{md} \leq 0.1\), and that the channel sensing time \(\tau \leq 2\) seconds. Since \(N \approx \tau f_s\), where \(f_s\) is the sampling rate, which may depend on the sampling frequency of the analog-to-digital converter (ADC) and the FFT (fast Fourier transform) bin resolution, \(N\) cannot be increased beyond \(\tau f_s\). In an experimental energy detection implementation [42], \(f_s\) is selected as \(f_s = 62.5\) kHz which may be a typical test-bed FFT bin resolution for moderate or high SNR. However, \(f_s\) can take several mega-hertz in other typical system implementations, e.g., some advanced ADCs can operate at \(f_s = 20\) MHz [43], 500 MHz [44], which may benefit low-SNR sensing. In our work, we limit \(f_s = 1\) MHz, and thus the maximal value of \(N\) is \(2 \times 10^6\) for 2 seconds of sensing time.\(^6\)

\(^6\)Since we only consider the sensing but not the subsequent processing, 2 seconds is used as a reference sensing time. For a fixed \(N\), sensing time can be proportionally reduced by using a higher sampling rate, e.g., we can have \(2 \times 10^6\) samples within 10 milliseconds at \(f_s = 200\) MHz as in [45].
Since analytical and simulation results in Fig. 5, Fig. 6, and Fig. 7 perfectly match, we only use the analytical results to generate Table III.

The optimal threshold, $\lambda^*$, is calculated based on low-SNR analysis in Section IV. Recall that an optimal threshold can be found only when $\lambda^*_f \leq \lambda^*_md$, which is equivalent to $N \geq N_s$ where $N_s$ is the minimum number of samples to have a feasible detection threshold that satisfies both requirements on false alarm and missed-detection probabilities. Under this condition ($N \geq N_s$), we may have three possible cases such as (i) $\lambda^*_f \leq \lambda^*_md \leq \lambda^*_c$; (ii) $\lambda^*_f \leq \lambda^*_c \leq \lambda^*_md$; or (iii) $\lambda^*_c \leq \lambda^*_f \leq \lambda^*_md$. As examples given in Fig. 5, Fig. 6, and Fig. 7, we do not have the third case.

Based on our analytical results in Fig. 5, Fig. 6, and Fig. 7, the regions of $N$ for different possible cases are shown in Table III. Table III also includes the minimal sensing time to have a feasible detection threshold when $f_s = 1$ MHz, given as $\tau_{\min} = N_s/(1 \text{ MHz})$, and the minimal sampling rate to have a feasible detection threshold when the sensing time is 2 seconds, given as $f_{s,\min} = N_s/(2 \text{ sec})$. We use two cases in Fig. 5: AWGN and Rayleigh fading cases, as examples. For the AWGN channel, there is no feasible detection threshold when $N < N_s = 66345$. When $N \in [66345, 66747]$, we have $\lambda^*_f \leq \lambda^*_md \leq \lambda^*_c$, the optimal threshold is determined by the missed-detection probability requirement, and thus, in this region of $N$, $P^*_md$ keeps at 0.1, and $P^*_f$ slightly below 0.1. When $N \geq 66748$, we have $\lambda^*_f \leq \lambda^*_md \leq \lambda^*_d$, and the optimal threshold is determined by minimizing the total error rate. For Rayleigh fading channel, there is no feasible detection threshold when $N < N_s = 1511174$. When $N$ varies from $N_s$ to $2 \times 10^6$ (the maximal number of samples when $f_s = 1$ MHz and sensing time $\tau = 2$ seconds), we have $\lambda^*_f \leq \lambda^*_md \leq \lambda^*_c$, and the optimal threshold is determined by the missed-detection probability requirement, and thus, $P^*_md$ keeps at 0.1

---

Fig. 5: Analytical error rates (lines) and simulated error rates (discrete marks) at the optimal threshold value (total error: $P^*_e$; false alarm: $P^*_f$; and missed-detection: $P^*_md$) versus the number, $N$, of samples at -20 dB average SNR for (a) AWGN; (b) Rayleigh; (c) Nakagami-4 fading channels.

Fig. 6: Analytical error rates (lines) and simulated error rates (discrete marks) at the optimal threshold value (total error: $P^*_e$; false alarm: $P^*_f$; and missed-detection: $P^*_md$) versus the number, $N$, of samples at -20 dB average SNR for SLC when $L = 2, 3$.

Fig. 7: Analytical error rates (lines) and simulated error rates (discrete marks) at the optimal threshold value (total error: $P^*_e$; false alarm: $P^*_f$; and missed-detection: $P^*_md$) versus the number, $N$, of samples at -20 dB average SNR for cooperative spectrum sensing when $K = 2, 3$, over Rayleigh fading.
In this region of $N$.

In the following, we focus on diversity-combining (SLC with $L = 2, 3$) and cooperative spectrum sensing ($K = 2, 3$), which can be used to increase the effective number of samples in the decision statistic without increasing the sampling rate. The Rayleigh fading channel is considered to establish the worse case scenario. From Table III, for two or three diversity branches in SLC, $N_s$ is reduced from $N_s = 1511174$ (no diversity) to $N_s = 156005$ or 62359, respectively, which results in the minimum sensing time at $f_s = 1$ MHz as $\tau_{\text{min}} \approx 0.16$ or 0.06 seconds, and the minimal sampling rate at $\tau = 2$ seconds as $f_{s, \text{min}} \approx 78.0$ kHz or 31.2 kHz, respectively. Similarly, for two or three cooperative nodes in a cooperative spectrum sensing network with $OR$ fusion rule, the minimum sensing time is $\tau_{\text{min}} \approx 0.16$ or 0.07 seconds, and the minimal sampling rate is $f_{s, \text{min}} \approx 82.4$ kHz or 35.4 kHz, respectively. Thus, to satisfy both IEEE 802.22 requirements on false alarm and missed-detection probabilities, diversity combining and cooperative spectrum sensing can significantly reduce the required sensing time and/or the required sampling rate.

In Fig. 8, simulation results are provided to compare our (optimal) threshold selection with a conventional threshold selection (calculated from $P_f = 0.1$). A Nakagami-4 fading channel with -20 dB SNR is considered. Note that conventional threshold selection does not guarantee a bounded missed-detection probability, which is evident from the figure. For example, when $N < 144842$, $P_{\text{md}} \leq 0.1$ is not satisfied, and thus, excess interference to primary users can be generated. When $N \geq 144842$, the optimal and conventional threshold selection can keep both $P_{\text{md}}$ and $P_f$ bounded by 0.1. But our optimal scheme has a lower total error rate because $P_f$ drops dramatically, improving spectral efficiency.

### D. Discussion for Case with Noise Uncertainty

Following [46], it is well known that uncertainty of the noise power level can significantly degrade the spectrum sensing capability of the energy detector. This has given rise to the so-called SNR wall phenomenon. According to [46], noise uncertainty is modeled as $\sigma_n^2 \in \left[ (1/\rho) \sigma_n^2, \rho \sigma_n^2 \right]$ where $\sigma_n^2$ is the nominal noise power and $\rho \geq 1$. Thus, if we denote $P_f$ and $P_{\text{md}}$ in (3) and (7) as $P_f[\sigma_n^2]$ and $P_{\text{md}}[\sigma_n^2]$, respectively, and denote the probability density function of $\sigma_n^2 \in \left[ (1/\rho) \sigma_n^2, \rho \sigma_n^2 \right]$ as $g_{\sigma_n^2}(\cdot)$, then the false alarm probability can be given as

$$P_f = \int_{(1/\rho)\sigma_n^2}^{\rho\sigma_n^2} P_f[\sigma_n^2] g_{\sigma_n^2}(x) dx,$$

and the average missed-detection probability can be given as

$$P_{\text{md}} = \int_{(1/\rho)\sigma_n^2}^{\rho\sigma_n^2} P_{\text{md}}[\sigma_n^2] g_{\sigma_n^2}(x) dx.$$ (27)

However, the analytical complexity depends on the nature of $g_{\sigma_n^2}(\cdot)$ expression, and it may not guarantee a closed-form and/or tractable expression for the threshold selection.

As an example, similar to [47], assume $\sigma_n^2$ to be a uniform random variable between $[(1/\rho)\sigma_n^2, \rho \sigma_n^2]$. Considering Nakagami-4 fading channel, we plot Fig. 9, based on (27) in which $P_{\text{md}}[\sigma_n^2]$ is given in (9), with $\sigma_n^2 = 1$ and $N = 2 \times 10^6$. Since larger $\rho$ means higher uncertainty, we can readily see that the performance degrades rapidly with higher $\rho$.

### VI. Conclusion

This paper analyzed the performance of energy detection in low SNR, deriving new missed-detection probability and AUC expressions. The criterion for optimal threshold was formulated to minimize the total error rate subject to bounded false alarm and miss-detection probabilities. Optimal thresholds were then derived for non-fading channels in closed-form and for multipath fading channels in approximate form. Diversity combining techniques and cooperative spectrum sensing were
shown to reduce the needed sensing time or sampling rate, enabling low-SNR detection. Low-SNR detection can play a useful role in the emerging cognitive radio networks.

While this paper considered a single secondary user and one primary spectrum band, this setup can be extended to cases with multiple secondary users and multiple primary spectrum bands. In this context, our analytical framework can be used to derive the detection performance and/or to select the detection threshold for any secondary user over any spectrum band. If a traffic model is specified for the secondary users, interesting future research topics may include optimal resource allocation to maximize the secondary network throughput.

APPENDIX

A. Proof of Theorem 1

As \( \lambda \) varies from \(-\infty \) to \( \infty \), \( P_f \) varies from 1 to 0. Therefore, the area under \( P_d \) versus \( P_f \) curve can be written as

\[
A = \int_0^1 \frac{1}{2} \text{Erfc} \left( \frac{\sigma_0}{\sigma_1} \text{Erfc}^{-1}(2x) - \frac{m_1 - m_0}{\sqrt{2}\sigma_1} \right) dx
\]

\[= \int_{-\infty}^{+\infty} \frac{1}{2} \text{Erfc} \left( \frac{\sigma_0}{\sigma_1} z - \frac{m_1 - m_0}{\sqrt{2}\sigma_1} \right) e^{-z^2} \frac{dz}{\sqrt{\pi}}
\]

where the second equality comes after substituting \( z = \text{Erfc}^{-1}(2x) \). Moreover, by using \( \text{Erfc}(x) = (2/\sqrt{\pi}) \int_{x}^{\infty} e^{-w^2} dw \), and with some algebraic manipulations, (28) can be re-written as

\[
A = \frac{1}{\pi} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} e^{-(w^2 + z^2)} dwdz.
\]

Now, we apply clockwise rotation to the \((w, z)\) axis through angle \( \theta \) to generate the \((u, v)\) axis where \( \tan \theta = \sigma_0 / \sigma_1 \), which is also equivalent to axis transformation of

\[
\begin{bmatrix}
    u \\
    v
\end{bmatrix} = \begin{bmatrix}
    \cos \theta & -\sin \theta \\
    \sin \theta & \cos \theta
\end{bmatrix} \begin{bmatrix}
    w \\
    z
\end{bmatrix}.
\]

This result gives

\[
A = \frac{1}{\sqrt{\pi}} \int_{-\infty}^{+\infty} e^{-u^2} du \frac{1}{\sqrt{\pi}} \int_{-\infty}^{+\infty} e^{-v^2} dv
\]

\[= \frac{1}{2} \text{Erfc} \left( \frac{m_1 - m_0}{\sqrt{2}(\sigma_0^2 + \sigma_1^2)} \right),
\]

where the second equality is due to \((1/\sqrt{\pi}) \int_{-\infty}^{+\infty} e^{-u^2} du = 1\) and the definition of the \( \text{Erfc}(\cdot) \) function. Expression (12) can be obtained from (29) by using \( \text{Erfc}(-x) = 2 - \text{Erfc}(x) \).

B. General Result to Achieve Minimum \( P_c(\lambda) \) in Any Channel Model

For any channel model (AWGN, Rayleigh, etc.), from \([48, \text{Property 3\&4, Page 33–34}]\), it can be seen that the ROC curve (i.e., \( P_d \) versus \( P_f \) curve) is a concave curve and is above curve “\( P_d = P_f \)” in a \( P_d \) versus \( P_f \) plot, which means that the complementary ROC curve (i.e., \( P_{md} \) versus \( P_f \) curve) is a convex curve and is below the curve “\( P_{md} + P_f = 1 \)” in a \( P_{md} \) versus \( P_f \) plot. An example of the complementary ROC curve is shown in Fig. 10, in which the dashed-dotted curve is the curve “\( P_{md} + P_f = 1 \)”. In the figure, when the threshold \( \lambda \) increases from 0 to \( \infty \), \( (P_f, P_{md}) \) moves along the complementary ROC curve from (1, 0) to (0, 1). Since the complementary ROC curve is convex and is below curve “\( P_{md} + P_f = 1 \)”, it can be concluded that when the threshold \( \lambda \) increases from 0 to \( \infty \), total error rate \( P_c(\lambda) = P_{md} + P_f \) first decreases (from value 1) and then increases (until value 1). So there exists one and only one point \( \lambda \) that minimizes \( P_c(\lambda) \), which is corresponding to the point with \( \frac{\partial P_c(\lambda)}{\partial \lambda} = 0 \).

C. Optimal Threshold \( \lambda^* \) for AWGN Channel

For the optimal threshold, \( \lambda^* = \arg \min \lambda P_c(\lambda) \) is achieved when \( \frac{\partial P_c(\lambda)}{\partial \lambda} = 0 \). With the aid of (1), and

\[
\frac{\partial}{\partial \lambda} \text{Erfc} \left( \frac{x - l}{q} \right) = -2e^{\frac{(x-l)^2}{\pi q^2}} \frac{q}{q\sqrt{\pi}},
\]
we can write
\[
\frac{\partial P_e(\lambda)}{\partial \lambda} = \frac{e^{-\frac{(\lambda-N(1+\gamma)\sigma_w^2)}{2\sigma_w^2}} - e^{-\frac{(\lambda-N\gamma^2)}{2\sigma_w^2}}}{\sqrt{2\pi N(1+\gamma)}\sigma_w^2} = 0.
\]
(30)
After some algebraic manipulations and taking the logarithm, (30) can be simplified into a quadratic equation of $\lambda$ as
\[
\lambda^2 - N\sigma_w^2\lambda - \frac{N\sigma_w^2}{2}(N\gamma + (1 + 2\gamma)\ln(1 + 2\gamma)) = 0.
\]
Thus, the solution $\lambda^*_a$ is given in (19) (here we omit the negative root since $\lambda \geq 0$).

D. Threshold Selections for Rayleigh Fading Channel

1) Threshold $\lambda^*_a$ for Rayleigh Fading Channel: By using the Taylor series expansions of Erfc($\alpha$), $e^{2\alpha}$, and Erfc($\alpha+a\alpha$), we can write $P_{md}^{Ray}(\lambda)$ in (21) as
\[
P_{md}^{Ray}(\lambda) \approx \frac{1}{2} \left[ 1 - e^{-\alpha^2}\text{Erfc}(\alpha) - ae^{2\alpha}\text{Erfc}(a)\alpha + \left( \frac{a}{\sqrt{\pi}} \right) a^2e^{2\alpha}\text{Erfc}(a) \right] \alpha^2 + O(\alpha^3).
\]
(31)
Setting $P_{md}^{Ray}(\lambda^*_a) = P_{th}$ for the above equation, $\lambda^*_a(\geq 0)$ can be selected as (22).

2) Threshold $\lambda^*_a$ for Rayleigh Fading Channel: For minimum $P_e(\lambda)$, we set $\frac{\partial P_e(\lambda)}{\partial \lambda} = 0$, which can be written with the aid of (3) and (21) as
\[
\frac{\partial P_e(\lambda)}{\partial \lambda} = \frac{e^{\lambda^2} + 2\alpha e^{\lambda\alpha} \text{Erfc}(a + \alpha) - e^{-\alpha^2}}{2\sqrt{2\pi N}\sigma_w^2} \lambda = 0
\]
\[
\iff e^{(\alpha + a\alpha)^2} \text{Erfc}(a + \alpha) = \left( \frac{2N}{\sqrt{\pi}} \right) \gamma.
\]
By using the Taylor series expansions of $e^{(\alpha + a\alpha)^2}$ and Erfc($\alpha$), we can write
\[
e^{(\alpha + a\alpha)^2} \text{Erfc}(a + \alpha) = e^\lambda \text{Erfc}(a) + \left[ 2ae^{2\alpha} \text{Erfc}(a - 2) \right] \alpha^2 + O(\alpha^3),
\]
which can be used to solve (32). The solution is given in (23), which achieves the minimum $P_e(\lambda)$.

E. Threshold Selections for Nakagami-$2$ Fading Channel

1) Threshold $\lambda^*_a$ for Nakagami-$2$ Fading Channel: By using the Taylor series expansions of $e^{-\alpha^2}$, Erfc($\alpha$), $e^{4\alpha\alpha}$, and Erfc(2$a + \alpha$), we can write $P_{md}^{Nak}(\lambda)$ in (24) as
\[
P_{md}^{Nak}(\lambda) \approx \frac{1}{2} \left[ 2ae^{2\alpha} \text{Erfc}(2a) \right] \alpha^2 + 8a^2 \text{Erfc}(2a) - \frac{1}{\sqrt{\pi}} \alpha^2 + O(\alpha^3).
\]
(33)
Setting $P_{md}^{Nak}(\lambda^*_a) = P_{th}$ for the above equation, $\lambda^*_a(\geq 0)$ can be derived as (25).

2) Threshold $\lambda^*_a$ for Nakagami-$2$ Fading Channel: For minimum $P_e(\lambda)$, after setting $\frac{\partial P_e(\lambda)}{\partial \lambda} = 0$ and some mathematical manipulations, we can write
\[
(a + \alpha)e^{(a + \alpha)^2} \text{Erfc}(a + \alpha) = -\frac{N\gamma^2 - 4}{4\sqrt{\pi}}.
\]
By considering the Taylor series expansion of $e^{(a + \alpha)^2}$ and Erfc($a + \alpha$), we can write
\[
\frac{2}{\sqrt{\pi}}(a + \alpha)^2 - (a + \alpha) \approx \frac{N\gamma^2 - 4}{4\sqrt{\pi}}.
\]
(34)
By solving the above equation, we can get $\lambda^*_a$ as given in (26), which minimizes $P_e(\lambda)$.

REFERENCES

Nandana Rajatheva (SM’01) received the B.Sc. degree in electronics and telecommunication engineering (with first-class honors) from the University of Moratuwa, Moratuwa, Sri Lanka, in 1987, and the M.Sc. and Ph.D. degrees from the University of Manitoba, Winnipeg, MB, Canada, in 1991 and 1995, respectively. He was with the School of Engineering and Technology, Asian Institute of Technology, Pathumthani, Thailand (1996–2001, 2005–2010) where he holds a visiting position now. Currently, he is an Adjunct Professor with the Department of Communication Engineering, University of Oulu, Oulu, Finland.

His research interests include signal processing, performance analysis, resource allocation for massive MIMO, relay, cognitive radio, and hierarchical cellular systems.
